Synonyms

[Autonomous living](#)

Definition

Independent living consists of participating in day-to-day life with full capacity to successfully choose courses of action and make decisions about where to live and how to participate in society without the oversight of another individual. Independent living requires having the skills necessary to manage life tasks including, but not limited to, household maintenance, time and money management, and self-care.

Independent living is also a philosophical viewpoint within the disability culture that promotes self-determination in individuals with disabilities and equal rights to participate in and contribute to society (The National Council on Independent Living 2010).

Index of Productive Syntax (IPSyn)

[IPSyn](#)

Description

Index of Productive Syntax (IPSyn) is a method for evaluating and quantifying the grammatical complexity of young children's spontaneous language samples. IPSyn is based upon the grammatical categories and developmental scheme of Assigning Structural Stage (Miller 1981). Individual utterances in a sample are scored for the occurrence of 60 different syntactic forms categorized under four subscales: noun phrase, verb phrase, question/negation, and sentence structure forms. Although IPSyn was developed for use with mainstream English speakers, it has been found to be a valid measure for children who speak African American English (Oetting et al. 2010).

IPSyn scores are calculated from children's spontaneous language samples. After a sample is elicited and recorded, a corpus is formed by transcribing 100 successive, intelligible utterances, excluding imitations, self-repetitions, and routines (stereotyped language that does not represent productive language use). Following guidelines stated in the IPSyn coding manual (Scarborough 1990), the transcript is then scored for 60 syntactic forms belonging to phrases and sentences that are categorized under four

subscales. The first two different occurrences of each form are credited. No additional credit is given for further occurrences in the sample. Certain early-developing structures are automatically credited if there is evidence in the transcript that the child has mastered later-developing structures in the same category. For example, if a child produces a question containing a wh-pronoun and verb (Q4), he also receives credit for intonationally marked question (Q1) and routine do/go or existence/name question (Q2). The points earned for each subscale are summed across all utterances, then added together to yield the total IPSyn score. No examiner qualifications are explicitly stated for this measure; however, the user must be familiar with English grammatical structures.

Historical Background

IPSyn was developed to provide a time-efficient means for measuring the grammatical complexity of children's utterances from the beginning of oral language through the period of early literacy. Other measures of grammatical complexity, such as Mean Length of Utterance (MLU, Brown 1973; Miller 1981) and Developmental Sentence Scoring (DSS, Lee 1974) had been and continue to be used for that purpose, but these other measures were criticized for their lack of scope and insensitivity to many important developmental language changes (Klee and Fitzgerald 1985; Klee and Sahlie 1986; Scarborough et al. 1991). IPSyn derived its grammatical categories and developmental scheme from Assigning Structural Stage (ASS, Miller 1981), a procedure generally hailed for its comprehensiveness. Furthermore, in contrast to measures such as MLU and DSS, IPSyn does not score every structure of every utterance within a corpus. Instead, it scans for a maximum of two structural types within each of its 60 syntactic forms. This approach results in an analysis that is adequately comprehensive yet not so time consuming as methods that evaluate all the structural forms produced by a child. IPSyn has been used in research on typical language development and disordered language development, including

autism (e.g., Tager-Flusberg and Calkins 1990; Tager-Flusberg et al. 1990). It is especially valuable to researchers using designs that require subject matching by language age (Scarborough et al. 1991).

Psychometric Data

No psychometric data are provided. IPSyn is not norm referenced.

Clinical Uses

As a clinical resource, IPSyn can be used to quantify and document linguistic changes that occur over time in successive language samples. A small database ($n = 15$) exists of typically developing children who were sampled at 24, 30, 36, 42, and 48 months (Scarborough 1990). Although these numbers fall short of what is needed for standardization, the available data show how IPSyn could be used for peer comparisons, if and when a larger standardization sample is gathered. Two computerized versions of IPSyn have been developed. In the version contained in Computerized Profiling (Long et al. 2006), the program performs an automatic analysis that must then be reviewed and edited by the user. Another version, designed to work with CHAT transcripts in the CHILDES system, is completely automatic (Sagae et al. 2005).

India and Autism

Savita Malhotra¹ and Ruchita Shah²

¹Fortis Hospital, Mohali, Punjab, India

²Department of Psychiatry, Postgraduate Institute of Medical Education and Research, Chandigarh, India

Historical Background

In India, the history of autism dates back to 1960s and is marked by initial sporadic efforts at clinical

descriptions and research followed by a more sustained progress in clinical services, research, and policies. The first case report of *autism* appeared in an Indian journal in 1962 (Bassa 1962). There were a few publications in the 1960s and 1970s referring to infantile autism, with a steady flow after the 1990s. Before the 1980s, awareness of the disorder, both among professionals and the general public was low, that increased gradually (Daley 2004). In the next two decades, i.e., from late 1980s to early 2000s, there were major developments in the field, in terms of services, legislation, policy, and capacity building. Nongovernment organizations and parent led organizations primarily for advocacy for children and adults with autism and their families were established (e.g., Tamanna, New Delhi; Action for Autism, New Delhi). Soon, these organizations forayed into spreading awareness, providing special educational services, resource building through training of teachers, and later quality research (Barua and Daley; Daley 2004). Alongside, two major developments occurred, the enactment of the National Trust for the Welfare of Persons with Autism, Cerebral Palsy, Mental Retardation and Multiple Disabilities Act, 1999 (NTA, 1999). This Act was formulated to provide for the constitution of a trust at the national level for the welfare of persons with autism along with other disorders and disabilities. The NTA was the first time *autism* was recognized as a distinct condition by legislators and policy makers. This opened the doors for government-driven and government-funded initiatives for the welfare of children and adults with autism in India. In early 2000s, the Rehabilitation Council of India (RCI), an autonomous body under the Union Ministry started a 2-year Diploma in Special Education (for autism spectrum disorders) course in four centers. The DSE (ASD) course designed in 2003 was the first of its kind to develop human resource in the field of ASD in India (RCI 2014).

The Central Board of Secondary Education (CBSE), an autonomous body under the Union Ministry of Human Resource Development, in 2009, introduced suitable modifications and concessions in the examination system to meet the special needs of students with disabilities such as

extra time for completion of examination paper, facility of scribe, and exemption from second and third language courses with choice of study subjects (CBSE, year not mentioned). The Right to Education (RTE) Act, 2009 and *Sarva Shiksha Abhiyan* (literal translation – Campaign for Education for All), the Government of India's flagship program for achievement of universalization of education, have a mandate for inclusive education for all children with disabilities including autism and intellectual disability (SSA, GOI). Parallel to this, the Rights of Persons with Disabilities Act (2016) that repeals the Persons with Disabilities (Equal Opportunities, Protection of Rights, and Full Participation) Act, (PDA) (1995) has included autism as one of the disabilities. The new Act provides a mandate for inclusive education, teachers' training, vocational training, and rehabilitation. Inclusive Education for the Disabled at Secondary Stage (IEDSS) was launched in April 2009, where assistance for the inclusive education of children with disabilities including autism, as well as funds for identification and assessment, assistive devices, allowance for transport, escorts, readers, uniforms, books, and stationery have been provided.

Another important development has been the recognition of child and adolescent psychiatry as an academic discipline. The Medical Council of India has made it mandatory for all the departments and institutes of psychiatry imparting post graduate degree (MD) in Psychiatry to have child and adolescent psychiatry services. There have been sustained efforts for providing specialized training in Child and Adolescent Psychiatry (CAP) to psychiatry postgraduates. A postdoctoral fellowship in Child and Adolescent Psychiatry was started in Vellore, Tamil Nadu, and National Institute of Mental Health and Neurosciences (NIMHANS), Bengaluru, followed by starting of a 3-year DM course in CAP in NIMHANS and Postgraduate Institute of Medical Education and Research (PGIMER), Chandigarh. The Medical council of India recognizes DM course in Child and Adolescent Psychiatry and has framed the curricular requirements and examination pattern in India. Also, a fellowship program in Developmental Pediatrics and a DM course in Pediatric Neurology have been started at PGIMER, Chandigarh.

Legal Issues, Mandates for Service

The National Trust (NT) established under the NTA, 1999 is an autonomous organization that aims to enable and empower persons with disability (including autism) to live independently and within or as close to the community to which they belong through its various agencies and schemes. The latter include scholarships, training, employment assistance, and health insurance among others. The Trust promotes measures for the care and protection of persons with disability by appointment of guardians and trustees, facilitates realization of equal opportunities, protection of rights, and full participation of these individuals and thus shares some aims with that of PDA, 1995. It also extends support to registered non-governmental organizations to provide need-based services ([National Trust](#), year not mentioned). However, the main aim of the NT remains to answer the worry of parents, "*What will happen to my child when I am no more?*"

The provisions of the Rights of Persons with Disabilities Act (2016) aim to protect the rights of these individuals as envisaged in the United Nations Convention on the Rights of Persons with Disabilities (2006), lay down specific measures to promote and facilitate inclusive education, vocational training and employment, social security, health care, insurance schemes, and rehabilitation. Chapter 3 of the Act specifically deals with education of these individuals, such as mandate for establishing adequate number of teacher training institutions, training and employing teachers who are trained in teaching children with disabilities, training of professionals and staff to support inclusive education and making necessary changes in the curriculum and examination system (Rights of Persons with Disabilities Act, 2016).

Sharing the spirit of the previous two Acts, the RTE Act (2009) addresses the important right, i.e., right to full time elementary education of satisfactory and equitable quality in a formal school which satisfies certain essential norms and standards. As mentioned earlier, inclusive education for children with autism is one of the mandates. With the passage of the RTE Act, changes have

been incorporated into the SSA approach, strategies, and norms. These children are recognized as those with special needs – CWSN. Schools are required to employ trained resource teachers for inclusive education of these children. The RCI Act and the RCI provide for the training curriculum and program of these teachers.

Overview of Current Treatments and Centers

Professionals involved in care are psychiatrists, psychologists, pediatricians, speech therapists, and occupational therapists, who work either individually or in liaison with each other. Treatment and care is provided by both medical institutions and nongovernmental social organizations. In the government sector, most of the cases are seen in the departments of psychiatry and pediatrics of general hospitals and apex teaching institutes like Postgraduate Institute of Medical Education and Research (PGIMER), All India Institute of Medical Sciences (AIIMS), and National Institute of Mental Health and Neurosciences (NIMHANS), etc. Only a few of these departments (of psychiatry) run special child and adolescent clinics, while still fewer have dedicated child and adolescent psychiatric units. However, the number of departments establishing such services is steadily increasing. Still, lack of trained manpower remains a serious handicap (Malhotra and Vikas 2005). Also, there is no specialized center for autism run by the government.

Few private centers which provide specialist care are out of reach of common people (Malhotra and Vikas 2005). There are several treatment and educational centers run by NGOs or parent associations and societies. Some of these have made notable contributions such as promoting greater awareness among professionals, conducting teacher and parent training through courses, workshops, and live demonstrations. Action for Autism (AFA), Academy for Severe Handicaps and Autism (ASHA) are some of the important organizations. AFA practices “open-door teaching method” in which the techniques used around the world are tested and modified to the needs of

Indian children. However, overall, there is a huge skew with most centers located in metropolitan cities (for example, Mumbai alone has 80 registered centers, while 2–4 centers each in other states) and almost all centers are in the state capitals (complete list available at: Autism Information and Resource Centre, an initiative of the National Trust, <http://www.autismresourcecenter.in/Default.aspx>).

Majority of the treatment protocols involve parents and are aimed at training the parents. Principles are largely drawn from TEACCH approach and Applied Behavioral Analysis (Malhotra et al. 2002, 2010). The strategies include behavioral techniques aimed at enhancing eye to eye contact, reduction of maladaptive behavior, structuring time, activities and physical environment (Malhotra et al. 2002), sensory integration, speech therapy, and picture exchange communication systems (Malhotra et al. 2010). Parent counseling and emotional support to parents have also been integral to treatment (Malhotra et al. 2002). There have been few other therapeutic interventions, e.g., ComDEALL (Karanth et al. 2010), Makaton language program, used at select centers. Few centres for complementary and alternative forms of medicine such as homeopathy and Unani also offer treatment for autistic children. Also, many families, as high as 90% opt for or combine the use of complementary and alternative medicines (Krishnamurthy 2008).

Overview of Research Directions

As mentioned earlier, autism research can be dated back to 1960s and 1970s, though it progressed sluggishly before the 2000s. Malhotra and Vikas (2002), Malhotra (2006) and Vijay Sagar KJ (2011) have well-reviewed the research in autism in India in the preceding years. Since late 1980s, several descriptions and observational studies (such as Srinath et al. 1989, Kar et al. 1993, Jaydeokar et al. 1997, Malhotra et al. 2003) appeared from tertiary psychiatric centers across the country in reputed national and international journals. Research in epidemiology of ASD is sparse (Malhotra and Kate 2015) and a

cohesive picture of the prevalence and incidence of autism spectrum disorder is missing in India (Naik 2015). Relation between social maturity and problem behaviors in children with comorbid intellectual disability have been explored (Ganaie et al. 2015). Freeth et al. 2013 conducted a cross-cultural study on autistic traits in India, UK, and Malaysia.

Apart from epidemiological surveys, research areas include descriptions and observational studies, interventional studies, genetic and neurobiological research, health systems research, some culturally oriented research on pathways to care, professionals and parent experiences/orientation, and psychometric validation of autism scales, development of Indian scales (such as Indian Scale for assessment of autism, NIMH, India), reviewed extensively in two publications (Naik 2015; Malhotra and Kate 2015).

For example, there are studies dealing with intervention programs (e.g., parent training programs, PECS, ComDEALL) (Malhotra et al. 2002, 2010; Karanth et al. 2010). Neurobiological studies have included assessment of CSF biochemistry (Narayan et al. 1993) and urinary metabolites (Damodaran and Arumugam 2011), serum levels of transcription factor nuclear factor-kappa B (Naik et al. 2011), chemical analysis of nail and hair (Priya and Geetha 2011) and BERA (Shivashankar and Satishchandra 1989). Cerebral perfusion and metabolism has been studied using PET (Anil Kumar 2012) and SPECT (Gupta and B.V. Ratnam BV. 2009). Both the studies used age-matched controls, while the former study (Anil Kumar 2012) also evaluated its association to behavior and cognitive functioning. Also, there have been efforts focusing on genetics of autism, such as studying *Engrailed-2* gene (Manjunatha et al. 1989), serotonin transporter promoter variants (Guhathakurta et al. 2006), and folate metabolic pathway in Indian patients (Mohammad et al. 2009) and relation to fragile X (Sen et al. 2010; Balasubramanian et al. 2009; Suvrathan and Chattarji 2011).

Socio-cultural issues including parental experiences and perspectives, met and unmet needs of families, parental stress, coping, and parenting styles (Desai et al. 2012; Divan et al. 2012;

Tripathi 2015; Minhas et al. 2015) have been explored. Daley et al. (2014) have attempted to explore routines of adults with autism using a mixed methods approach.

Besides these studies, work has been done in the areas of psychometric validation of autism scales and lately, development of indigenous scales. Recently, Indian Scale for Assessment of Autism (ISAA) has been developed as a measure of symptom severity, and there have been several studies reporting on its reliability and validity (Chakraborty et al. 2015; Mukherjee et al. 2015; Patra and Arun 2011). The ISAA has been recommended for purposes of disability certification as per the guidelines of the Government of India (GOI Notification dated 25th April, 2016). The International Clinical Epidemiology Network (INCLIN) Trust group has developed the INCLIN Diagnostic Tool for Autism Spectrum Disorder (INDT-ASD), and it has been found to have good diagnostic accuracy (Juneja et al. 2014). The tool has been recommended for use in conjunction with the ISAA (GOI Notification dated 25th April, 2016), though larger field trials are needed for ascertaining the psychometric properties and diagnostic stability of the tool (Wong and Singhal 2014).

There have been a few interventional studies. Malhotra et al. (2002) offered a parent intervention package including behavioral, supportive, and educational techniques, delivered in 3–6 sessions of 45–60 min each and found that on the whole parents found this brief contact helpful. Malhotra et al. (2010) studied effects of picture exchange communication system on communication and behavioral anomalies in autism and found improvement in the target behaviors. Karanth et al. (2010) studied the efficacy of an indigenous early intervention program for children with autism spectrum disorders that specifically targets developmental issues in the areas of motor, communication, cognitive, social, and emotional skills in a small sample of 30 children. A small cross-sectional study that used an autism treatment evaluation checklist pointed towards the need for training in order to improve the communication and social interaction in children with autism (Ghosh et al. 2015). Divan et al. (2015) developed

the parent-mediated intervention for Autism Spectrum Disorder in South Asia (PASS) intervention, which is a cultural adaptation of the Preschool Autism Communication Therapy (PACT) program. Harshini and Preeti (2017) have proposed an interventional model deliverable at primary care in nonspecialist setting that focuses on parental training at the center focusing on joint attention, imitation, adaptive and social engagement skills and encouraging parents to engage the child in home-based training. Overall, in resource-limited settings such as those in India, it is intuitive to consider parents as the instrument for therapeutic intervention. However, robust studies are needed to establish the efficacy of indigenously developed or culturally adapted intervention programs before these can be recommended on a larger scale.

In 2010–2011, the Indian Council of medical Research (ICMR) announced plans to conduct extensive and in-depth research in the area of ASDs. Since then, several projects addressing early diagnosis and prevalence studies, evolution of diagnostic thresholds criteria for Indian population, standardization of multidisciplinary assessment, functional imaging studies, correlational studies with neuro-psychiatric morbidities, standardization of therapeutics, genetic studies (e.g., REELIN gene, MeCP2, β -amyloid precursor protein), biochemical markers, intervention studies and services for care, development of training modules for parents & children, development of modules of care at schools and home, special education and remediation, and speech therapy and sensory integration studies have either been launched or are in the pipeline. ICMR has also initiated collaborative projects with Autism Speaks (<http://www.icmr.nic.in/>). The development of INCLIN tools and PASS intervention has been the result of such international collaborations. The NIMH, Secunderabad, have started work on a project studying effectiveness of sensory integration therapy on sensory processing and adaptive behavior (NIMH; <http://www.nimhIndia.org/R&D%20ongoing%20projects%2012-13.pdf>). NIMHANS Bangalore is working towards developing a hospital-based Autism Registry.

Policy and Training

As mentioned earlier, the RCI started Diploma in Special Education (ASD) in four centers; the government run premier institute, National Institute for Mentally Handicapped (NIMH), Secunderabad, India, being one among these. Since then, the course curriculum has been revised every 5 years, the latest revision being in 2014 (RCI, 2014). This 2-year course is now conducted in over 20 institutes recognized by the RCI. The trained teachers can work in regular schools as resource teachers, in special educational settings, and in clinics and hospital-based departments. The RCI along with certain organizations such as Action for Autism conducts periodical workshops and seminars for awareness and training of teachers. Under the SSA program, there are detailed modules and curriculum for training of teachers in educational and behavioral methods for autism, intellectual disability, and other disabilities (Sarva Shiksha Abhiyan website). Also, the postdoctoral fellowships and DM courses shall increase the specialized manpower required in this field in the near future.

With the mandates of the existing and soon to be enacted Acts, deliberately designed policies for capacity building and research, and sustained efforts across various fields such as medical research, education and rehabilitation, and legal, the stage is set for the scenario of autism services and research to change dramatically for the good in India.

Definition

Individual Education Program

An Individualized Education Program (IEP) is provided to students with disabilities under the Individuals with Disabilities Education Improvement Act (IDEIA). Current law (IDEIA) dictates that all students who are eligible for educational supports and specialized services have an IEP. The IEP is a legal document outlining the necessary services and supports for children with disabilities (i.e., who have an educational eligibility) ages 3 years through 22 years. IEPs are created in collaboration with parents, teachers, and

therapists working with the student. The purpose of the IEP is to outline educational goals, supports, services, and placement for individual students with disabilities and identify who is responsible for carrying out the student's program. An IEP serves as the framework for individualized instructional programs for students with disabilities. The IEP addresses all of a student's educational needs. It is a written program of educational services and supports developed for each student eligible for services in accordance with the criteria outlined by each state's board of education. The IEP includes procedural safeguards for parents of students with disabilities. The procedural safeguards outline the rights of students and parents. Parents are given a copy of their procedural safeguards at each IEP meeting. The procedural safeguards are determined by each state board of education. These include (but are not limited to) free and appropriate public education for all children age 3 and older, prior written notices for all meetings and decisions, a description of instructional and placement options, and descriptions of all evaluation procedures.

An IEP is required for all students older than 3 years who need specialized services. In most states, children younger than 3 who have an Individual Family Service Plan (IFSP) will transition to an IEP at age three. In some states, this transition occurs at age 5 or once the child enters kindergarten. The transition from an IFSP to an IEP always involves a reevaluation (i.e., parent and team input, informal assessments and observations, and standardized assessments). The eligibility determinations are made by the state-appointed evaluation teams based on the extent to which the disability impacts the students' educational performance.

Historical Background

IEPs are mandated by federal law, specifically the Individuals with Disabilities Act, which was recently amended in 2004. The major purpose of this law is to ensure all children with disabilities to have access to free and appropriate education

(FAPE). The IEP outlines the services and supports needed to ensure the child receives FAPE.

Current Knowledge

IEP Process

For students 3 years and older, the initial IEP process begins with an evaluation of the child's present level of development. An eligibility determination is made based on the assessment information gathered. This includes information gathered through parent interviews, informal classroom observations or assessments, and formal or standardized assessments. The state identified evaluation team determines eligibility for services based on the extent to which child's disability negatively affects educational performance. For example, the evaluation team might determine a child's autism is negatively affecting his ability to communicate, interact with others, access the general education curriculum, access materials in the classroom, and meet grade level expectations. The team might determine this child meets the eligibility requirements and needs specialized services. However, not all children with a medical diagnosis of autism will be eligible for educational services. For example, the evaluation team might determine a child with higher functioning autism (i.e., has above average IQ) can access the general education curriculum, materials, and have positive interactions with peers and adults with the typical classroom-wide structure and supports. Once the child is determined to be eligible for specialized services and an IEP is developed, the child's eligibility is reevaluated every 3 years. The student's IEP is revised each year at an annual review.

IEP Components

There are several components to an IEP (e.g., the educational team, eligibility category, placement, accommodations, strengths, goals, and services). These will be described in more detail.

IEP Team

The student's educational team is made up of a variety of individuals who collaborate to develop

an educational program that will meet the student's needs. The IEP team for students with autism should include the parents, general education teacher, special education teacher, and school district representative (e.g., the case manager, guidance counselor, administrator, or professional at the district level). Depending on the needs of the student, the IEP team also might include an autism specialist, speech/language therapist, occupational therapist, school psychologist, behavior specialist, and the student when appropriate. The special education teacher is a key member of the IEP team for students with autism (Hall 2007). Thus, special education teachers serving students with autism must have specific experience and coursework related to evidence-based practices for students with autism. Occasionally, school districts will hire autism specialists (i.e., school personnel with specific experience and training in evidence-based practices with students with autism) to support students with autism and help teachers in assessment, instructional planning and implementation, and progress monitoring of students with autism (Hall 2007). In sum, the purpose of the IEP team is to determine the extent of the student's needs, design an instructional program, implement the program, evaluate the program, and ensure the student receives the appropriate supports and services. Thus, the role of the IEP does not begin and end at the IEP meeting – it is an ongoing effort. Effective communication among team members is essential to ensure the IEP is followed and the child is making appropriate progress toward goals and objectives.

Educational Needs

The next major section of the IEP is the students' educational needs. This section indicates the student's eligibility category and specific information related to how the disability impacts the child's educational performance. Eligibility categories might include autism, other health impaired, emotional delays, cognitive delays, specific language impairment, speech impairments, visual or hearing impaired, or learning disability. This section includes a statement with specific information related to how the student's disability

impacts his educational performance or academic achievement.

Current Assessment Information

This section includes a statement about the student's present level of development, functioning, and educational performance, including information about what skills the student has mastered and what skills are developing. This section also should include information related to the child's current academic and behavioral repertoire, learning style, interests, and the impact of the student's disability on academic, social, adaptive, communication, or motor skills. This can include information related to assessment results, discipline reports, grades, observational notes, and attendance information. The student's academic and behavioral strengths also should be clearly delineated in this section. Parents *and* teachers should provide information about the student's behavioral and academic strengths. This assessment information should be directly linked to instructional planning. The team will develop a list of areas of instructional priorities based on this assessment information. Successful instructional programs are directly linked to the student's strengths, assessment results, interests, learning style, and parent priorities and concerns (Boutot and Myles 2011).

Educational Needs

The next section on the IEP delineates the student's needs, instructional priorities, and goals. The student's needs are developed based on the assessment results, levels or area of impact of the disability, or academic performance. Annual goals and short-term objectives should be written for each area in which the student has needs. The areas of need for students with autism should include communication, social skills, and affected academic areas (e.g., reading, math). Many students with autism will need goals in fine motor, gross motor, or adaptive skills (e.g., independent functioning). The student's needs should be directly linked to the student's goals. Goals are the skills that the student will attain within the year or other specified amount of time. Goals should be functional, generative, measureable,

and instructional. Functional goals are directly related to skills the student will need for independent performance within daily routines and activities. Generative goals are related to skills the child will need across settings, people, materials, and activities. Measurable goals are clearly operationalized so that the student's progress can be clearly and efficiently monitored over time. Instructional refers to goals that will occasion opportunities for teaching throughout the student's day. Goals also should be written in a positive manner with clear, professional language (e.g., instead of "Elisa will stop hitting peers," the goal should read "Elisa will verbally ask a teacher for help").

Examples of annual goals for children with autism are:

1. For a preschooler: Sammy will appropriately respond (e.g., verbally or with gestures) to social initiations from a peer during classroom routines and activities. We will know he can do this when he appropriately responds to 5 peer initiations per day for 3 consecutive days.
2. For an elementary school student: Juan will follow classroom rules and directives (e.g., sit in chair, raise hand to ask questions, walk in the halls, etc.) given visual and verbal prompts. We will know he can do this when he follows 10 classrooms rules and directives for 2 days in a row.
3. For a high school student: Trevonte will ask questions of others regarding topics initiated by self or others to sustain conversation. We will know he can do this when he participates in five conversations per day for 3 consecutive days.

Accommodations or Modifications

This section delineates accommodations or modifications necessary to support the student's learning. Accommodations are changes made to the instruction or assessment to support the student and provide access to the general education curriculum without altering the content. Accommodations for students with autism might include visuals or graphic organizers, specialized seating arrangement, visual rather than written responses,

adapted keyboards, or having material read aloud. Accommodations do not change grade level or academic expectations. Modifications refer to changes made to the assessment or general education curriculum to meet the needs of the student. Accommodations are required by law to ensure students with disabilities have an equal opportunity to learn and access the general education curriculum. Modifications are made when the expectations are not appropriate for the student. Examples of modifications for students with autism might include the following: a student works on addition, while peers work on division; a student stacks or sorts materials, while peers work on a science experiment; or a student is given a test on continents, while peers are tested on geography or countries across the world. Modifications should target the highest level possible to meet the student's needs (i.e., closest to the general education content as possible) and only used when absolutely necessary.

Related Services

The next section of the IEP describes the services necessary to support the student and supplement the services provided in the classroom. Related services are required to ensure the student is successful in the classroom. Related services for students with autism might include speech/language therapy, occupational therapy, assistive technology, transportation, and counseling. This section will describe these services in detail. The related services section includes the frequency of services (e.g., twice per week for 30 min), the location of these services (e.g., classroom, therapy room), the type of services (e.g., direct service to the individual child, group services with the child and other children with disabilities, or consultation to the teacher or parent), and the person providing these services. Indirect services (i.e., consultation and coaching) are often provided by autism specialist to students with autism in general or specialized classrooms. This might include consultation to the general education teacher about designing a predictable, visually rich environment to support the student with autism or the special education teacher about implementing an evidence-based strategy for teaching communication or social

skills. These services should be provided directly in the classroom when appropriate to support the student with autism in accessing the classroom curriculum and interacting with peers and materials.

Assistive Technology

The next section on the IEP is related to assistive technology for students with disabilities. This includes technologies used by the student to function within the classroom and community. For students with autism, this might include augmentative communication devices, computer software to enhance academic performance, or the use of personal digital assistants (PDAs) to promote independent transitioning and following schedules.

Setting

The IEP also will indicate the setting(s) in which the IEP will be implemented. This is referred to as the educational placement. Placement is not based on district availability or preferences. The IEP team will determine the student's placement based on the student's strengths and needs. Special education law requires that all students with disabilities be educated in the least restrictive environment and with their typical peers to the maximum extent possible. The law requires the general education classroom to be considered first, and if the student is not included in the general education, the IEP should document and specify reasons why. A continuum of placements must be considered from least restrictive (general education classrooms) to more restrictive (e.g., special classroom or school). The IEP team should consider general education classroom with embedded special education services, general education classroom with pull-out to a resource or special education classroom for part of the day, special education classroom within a general education school, or specialized school. In rare cases, service will be provided in an institution or hospital. Extensive research supports the inclusion of student with disabilities in the general education classrooms. For example, inclusive classrooms provide a context for implementing evidence-based practices, occasional social interactions

and communication among students with autism and their typical peers, which represent core skill deficits for children with autism, and research has documented more positive attitudes toward disabilities by peers when students with disabilities are included in the preschool environment (Dawson and Osterling 1997; Strain et al. 2002). If the placement is not a general education classroom, the IEP must specify the amount of time the child will participate in the general education classroom, document that opportunities for the student to interact with typically developing peers will be provided, and include a statement specifying that the least restrictive environment was considered.

Positive Behavior Supports

There also is a section on the IEP that requires the team to indicate if positive behavioral supports have been considered for the student with autism. This is an important service for many students with autism, particularly students who display stereotypic behaviors (e.g., repetitive hand flapping, body rocking), or challenging behaviors (e.g., which are often due to delays in functional communication and social skills) that might interfere with learning. This section will describe the supports (e.g., preventative strategies, replacement skills, and responses to challenging behaviors) and implementation plan.

Evaluation

The IEP also includes a section specifying how student progress will be measured and evaluated. Appropriately written goals and objectives will embed an evaluation process. However, this section ensures the student's progress is intentionally and systematically monitored over year. Progress on each goal must be measured and documented.

Postsecondary Transition

The IEP for students with autism who are 14 years old must include a section for the student's post-school plan or transition to adult care or services. The IEP team considers the student's need for transition services and documents the discussion. When appropriate, the IEP will include a statement of the needs for services and a transition

planning form. This form requires the IEP document the discussion about the student's transition to adult life after school. The form will include a postsecondary vision (e.g., the student's goals for adult life); disability-related needs; plan for supporting the student's self-determination, academic, and adaptive skills to support postsecondary vision; and the roles of school personnel, family, student, and community providers in supporting the student.

504 Plans

Students with disabilities who require accommodations must have a written plan. If the accommodations are considered reasonable, the student can have a 504 plan rather than a full IEP. The 504 plan also is developed by the student's educational team, but requires only minimal accommodations to access and succeed within the general curriculum. For students with autism, this might include a digital timer, longer testing time, or regular breaks during the day.

Future Directions

Summary and Future Directions

An Individualized Education Program (IEP) is the legal documentation of an educational plan developed with a team of professionals based on the strengths and needs of one child. IDEIA mandates that all children with special needs have a right to an IEP and free access to appropriate public education. Effective IEPs ensure that children with autism receive equitable education (the same as children without disabilities) in the least restrictive environment possible. Future research should examine components of effective IEPs and strategies for developing collaborative, effective IEPs.

Individualized Family Service Plan

Erin E. Barton
University of Colorado Denver, Denver, CO,
USA

Definition

An Individualized Family Service Plan (IFSP) is a legal documentation of the early intervention process for children with disabilities younger than 3 and their families. The IFSP guides the early intervention process in accordance with Part C of the Individuals with Disabilities Act (IDEA). Part C of IDEA is a federal grant program that supports states in operating a comprehensive system of early intervention for children younger than

3 years old with or at risk for disabilities and their families. As with the IEP (Individual Education Program), the IFSP is completed by a team of professionals (including the child's family and caregivers); the IFSP documents services necessary to support the family and build the family's capacity to help their child grow and develop. An IFSP is required for all children younger than 3 years who are receiving Part C early intervention services. In most states, children younger than 3 who have an IFSP will transition to an IEP at age three. In some states, this transition occurs at age 5 or once the child enters kindergarten, in which case the children have an IFSP until they are 5 years old. The transition from an IFSP to an IEP always involves a reevaluation (i.e., parent and team input, informal assessments and observations, and standardized assessments).

IEP Versus IFSP

IFSPs and IEPs are legal documents outlining the services needed for children with disabilities from birth to age 3 and from age 3 through 21, respectively. The IFSP and IEP are similar in that they are developed by a team for an individual child or student and include the goals, interventions, and supports necessary to support their learning. However, IFSPs are uniquely designed to revolve around the individual family's concerns, priorities, and resources. IFSPs include child and family outcomes relating to supporting the child's development, whereas IEPs are focused only on the student and his/her academic performance. IFSPs identify the family's natural setting and document how and when services will be provided in the family's natural settings (i.e., home, parks, child care). Also, IFSPs have an additional section (as compared to IEPs) where the non-Part C services required by the family are listed along with the funding sources for those services. IEPs focus on the special education and related services in schools. The final difference between IEPs and IFSPs lies within their purpose. In sum, the purpose of the IFSP is to identify and document the supports needed to strengthen the family's capacity to promote their child's development, whereas the IEP outlines the supports and services to be provided by professionals within schools to

promote the student's academic performance (McWilliam 2010; McWilliam et al. 1998).

Historical Background

The Individual Family Service Plan (IFSP) is part of a system of federal and state special education laws. The federal law, the Individuals with Disabilities Education Act (IDEA), specifies the IFSP and defines the basic components that must be in an IFSP. Each state further defines the specific children and families eligible for Part C services and the IFSP components.

Current Knowledge

IFSP Process

For children younger than 3, the initial IFSP process begins with an evaluation of the child's present level of development. An eligibility determination is made based on the assessment information gathered. Eligibility determinations are state-determined. Thus, although all states and eligible territories currently provide Part C services, the children and families who are eligible for these services differs across states. A few states provide Part C services to children younger than 3 who are at risk for delays and children who have delays. Eligibility determination is made based on information gathered through parent interviews (e.g., Routines Based Interview, McWilliam et al. 2009; Routines-based assessment, Woods and Lindeman 2008), informal observations or assessments in natural settings, and formal or standardized assessments. Once the child is determined to be eligible for specialized services and an IFSP is developed, the child's eligibility is reevaluated every year. The IFSP team reviews and evaluates child and family's progress on IFSP outcomes at least every 6 months.

IFSP Components

There are several components to an IFSP (e.g., the team, current assessment information, family concerns, outcomes, etc.). These will be described in more detail.

IFSP Team

The child's educational team is made up of a variety of individuals who collaborate to develop a plan to meet the child and family's needs. The IFSP team for children with autism might include the parents, autism specialist, early interventionist, speech/language therapist, and service coordinator. Depending on the needs of the child and family, the IFSP team also might include a behavioral specialist, social worker, or psychologist. If the child spends more than 15 h per week in child care, the primary care provider from the child care setting should be included on the team (McWilliam 2010). The purpose of the IFSP team is to build a collaborative relationship with the family and determine the supports necessary to build the family's capacity to promote their child's development. For children who spend more than 15 h per week in child care, this includes supporting the primary care providers in the child care setting. As with the IEP team, role of the IFSP team does not begin and end at the IFSP meeting – it is an ongoing effort. Effective communication among team members is essential to ensure the IFSP is followed, families (or child care providers) are receiving the supports they need, and the child and family are making appropriate progress toward outcomes. One member of the team is identified as the primary service coordinator, who organizes and is responsible for ensuring implementation of the IFSP. Effective IFSP teams are guided by a transdisciplinary model of service delivery (i.e., one professional provides the weekly supports with back-up from other team members (McWilliam 2010)) and use an interagency approach (involves professionals from a several agencies).

Present Levels of Development

The next section of the IFSP outlines the child's present level of development. Each family will receive a multidisciplinary assessment of their child's unique strengths and needs. The child's present level of development should be assessed across five areas: motor, cognitive, communication, social emotional, and adaptive. This information should be gathered from valid and reliable assessments and authentic observations

in the natural environments. This section should also include parent or caregiver reports about their child's preferences, strengths, and characteristics.

Family's Resources, Priorities, and Concerns

The IFSP team also will gather information about the family's resources, priorities, and concerns (e.g., Family Interest Survey, Cripe and Bricker 1993). This information can be gathered through informal conversations, interview, or assessments. A statement about the family's concerns, priorities, and resources related to enhancing their child's development is required on all IFSPs.

Child Outcomes

The next section on the IFSP delineates the child outcomes. These are developed by the IFSP team (including the family) and directly related to the assessment information. Many young children with autism will need outcomes related to social or communication skills. Outcomes should be functional, generative, measureable, instructional, and participation-based. Functional goals are directly related to skills the child will need for independent performance within the family's daily routines and activities. Generative goals are related to skills the child will use across the family's routines and materials at home, the various community settings the family and child participate in, and people the child interacts with. Measurable goals are clearly operationalized to directly link to an intervention plan for the family and so that the child's progress can be efficiently monitored over time. Instructional goals refer to behaviors and skills the family will have opportunities to practice with the child across their daily routines with the materials they have at home. Finally, goals for young children should be participation-based. This means they explicitly refer to the context in which the skill is needed to ensure everyone on the team understands how the goal helps the child participate in the family's daily activities and routines

(McWilliam 2010). The criteria, procedures, and timelines for measuring progress also are included in this section. Collaboration in developing child outcomes is essential to build the family's capacity and increase the child's participation in the family's routines and activities. Example child goals are:

1. Kenan will participate in meals, playtime (after bath, after breakfast), and routines (diapering, bath time, getting dressed, waking up) by looking at mom or dad and babbling. We will know he can do this when he looks at mom or dad's eyes and babbles three times during five activities per day for 1 week.
2. Luke will participate in breakfast, lunch, mid-afternoon snack, and dinner by feeding himself independently. We will know he can do this when he uses his hands to pick up 15 small pieces of food to put in his mouth or uses his hands to pick up his spoon to put at least 10 bites of soft foods in his mouth at each meal for 1 week.

Goals should be written so they can be embedded into daily routines and natural settings, emphasize functional skills, and increase participation in activities and settings.

Family Outcomes

The IFSP must include at least one family outcome. As with the child outcomes, the family outcomes also are based on the family's priorities, resources, and concerns. These outcomes are explicitly focused on setting goals to build the family's capacity to support their child's growth and development. The family selects their outcomes based on things they would like to start working on, including the any resources or needs identified through the assessment. Example family outcomes might be (adapted from McWilliam 2010):

1. Janice will keep Maize engaged during at least 30 min of church each week for a month so Janice can start going to church again.

2. All five members of the McDonalds family will spend 1 h each night engaged in a fun activity with the TV off.
3. Anne will rate Alyse's bedtime routine as successful and easy with 4 months.

These family outcomes are based on specific concerns reported by the family, directly related to the families current priorities, and developed in consideration of the family's available resources and include measurable criterion to ensure the team will know when the outcome has been achieved.

Natural Environments

The next section of the IFSP identifies the settings where the family spends most of their time and the activities they enjoy. The natural setting might be the home, child care, relative's house, or community center. The family's valued activities and routines are listed to identify needs and opportunities for learning. All child outcomes should be developed with the natural setting, valued activities, and daily routines in mind; the outcomes should support the child's independent participation in family routines and activities. Also, all service and supports should be provided in the natural settings. In fact, IDEA Part C regulations state: "To the maximum extent appropriate to the needs of the child, early intervention services must be provided in natural environments, including the home and community settings in which children without disabilities participate" 34CFR 303.12(b), and "natural environments means settings that are natural or normal for the child's age peers who have no disabilities" 34CFR 303.18.

Services

The next section of the IFSP delineates the specific services and supports needed to support the child and family in achieving the stated outcomes. The primary service provider will provide or coordinate the provision of material, emotional, or informational supports to build the family's capacity to promote their child's development.

Services and supports are provided through family coaching in the natural setting (often referred to as home visiting) or consultation with the child care center within the child's daily routines. Material supports might include necessary equipment (e.g., a communication device, supported seating) or basic necessities (e.g., calling an agency to help the family get diapers or housing subsidies). Emotional support might include sensitivity to the family's culture and needs, positive feedback, and responsiveness (e.g., listen to the family, respond to calls, or emails quickly). Informational support might include information about the child's disability, community resources, and strategies for providing learning opportunities throughout the day. In general, services and supports should be provided directly to the family rather than to the child (Jung 2003). In this manner, the family is supported and given the resources to provide the "intervention" all day long across daily routines and activities with relevant materials. Effective service providers recognize that the family can support their child's development by providing numerous natural learning opportunities throughout the day between scheduled home visits (McWilliam 2010). Also, supports and services should reflect the family's culture and experiences. This section also will specify the projected dates of when the services will begin, how often they will occur, and how long they will last.

Evaluation

The IFSP also includes a section specifying how the child and family's progress will be measured and evaluated. This section should include the criteria, procedures, and timelines used to measure progress toward outcomes. Appropriately written outcomes will include a measurable criterion (e.g., 5 times across 5 days, 10 times per day for 1 week). However, this section ensures the child and family's progress is intentionally and systematically monitored. Progress on each outcome must be measured and documented, and reviewed at least every 6 months. The team will assess progress and determine if the supports are effective or if changes need to be made to the

IFSP. As mentioned above, the IFSP is meant to delineate an ongoing process of support for the family and child to help the family recognize their own strengths, resources, and capacity to promote their child's development.

Transition Plan

The IFSP includes a section to plan for the transition to special education services (Part B of IDEA which refers to special education services for children 3 years and older) and an IEP, or other appropriate agencies or resources for when the child turns 3. The service coordinator must initiate this conversation and plan with the family at least 6 months prior to the child's third birthday.

Non-part C Services

The final section of the IFSP delineates the activities or services provided by agencies outside of Part C. This is meant to help the service coordinator and family integrate all service and supports. Occasionally, families are charged for these non-Part C services, which should be noted on the IFSP.

Future Directions

An Individualized Education Program (IFSP) is the legal documentation of a service plan developed with a team of professionals based on the strengths and needs of one child and their family. IDEA mandates that all children younger than three receiving Part C services have an IFSP. Effective IFSPs ensure that children with autism and their families receive early and intentional intervention in the natural setting to support the family's capacity to promote their child's development to prevent or alleviate further delays. Despite the plethora of research on the benefits of early, intentional intervention for children with or at risk for disabilities, early intervention (specifically effective family coaching) is a largely understudied topic. Future research should examine effective family coaching, home visiting, and strategies for developing effective IFSP.

Individualized Plan for Employment (IPE)

Ernst O. VanBergeijk

Vocational Independence Program, New York
Institute of Technology, Central Islip, NY, USA
Threshold Program, Lesley University,
Cambridge, MA, USA

Definition

An Individualized Plan for Employment (IPE) (also known as an Individualized Employment Plan [IEP]) is a contractual agreement between an individual with a disability and a state office of vocational and rehabilitative services. IPEs help inform the individual regarding what services they will receive and help them make informed choices regarding their vocational training. This information includes the cost, duration, and accessibility of potential services. This document is written collaboratively between the client and vocational rehabilitative counselor. The IPE must contain the following information: (1) the date that services begin and the date by which the vocational objective is to be achieved; (2) the specific services that are to be offered to the client or consumer; (3) objective criteria, evaluation procedures, and schedules for determining progress toward goals; and (4) a description of the Client Assistance Program (CAP) (Vision Aware 2010).

For each service described in the IPE, specific information must be listed. Each service must have a date by which the service will be initiated and a date by which the specific vocational goal will be reached. The IPE must describe the services offered to the client in detail. The vocational goals are to be written in a manner that is behaviorally oriented so that the vocational goal is observable and measurable. How the attainment of the goal will be assessed must be written into the IPE. The IPE should be reviewed at least annually (Joint Committee on Administrative Rules n.d.).

The list of services available to a client who is eligible for vocational and rehabilitative services from a state office includes the following:

- Counseling and guidance.
- Physical and mental restoration, including corrective surgery and ocular prosthetic devices.
- Vocational and other training services.
- Services to the family.
- Interpretive services for those who are deaf.
- Reading services.
- Personal adjustment services.
- Provision of telecommunications and other technical aids.
- Placement in suitable employment.
- Post-employment services if the client's job is in jeopardy.
- Assistance in obtaining occupational licenses, tools, equipment, and initial stocks for small businesses.
- Job coaching services.
- Assistance in obtaining other goods and services that could aid the client in obtaining employment.
- In addition, the vocational objective must contain a formal job title that is listed in the *Occupational Outlook Handbook*, with the code number, if available (Vision Aware 2010).

Current Knowledge

The range of unemployment figures varies from 50% to 75% for people with disabilities in general and over 90% for individuals with autism spectrum disorders.

Future Directions

A coordination of entitlements must be developed for young adults who are transitioning between secondary school and postsecondary education. There is potential conflict between the transition plans outlined in IDEA, the new provisions of the Higher Education Opportunity Act of 2008, and the Rehabilitation Act Amendments of 1998 in terms of which law or agency will pay for additional training if that training is conducted in an institution of higher education such as through a Comprehensive Transition and Postsecondary Program (CTP) at a college or university.

Individualized Transition Plan (ITP)

Paul Wehman¹ and Staci Carr²

¹Department of Physical Medicine and Rehabilitation, Virginia Commonwealth University, Richmond, VA, USA

²UniqueKids Inc, Moseley, VA, USA

Definition

Individualized Transition Plan, or ITP, is a plan based on informal and formal assessments that is used to identify the desired and expected

outcomes by students and their families once they leave school as well as the supports needed to achieve these outcomes. This plan is developed collaboratively with the student, caregivers, vocational educators, vocational rehabilitation counselors, and current IEP team members. A thorough plan will include the following: post-secondary education opportunities, employment opportunities, living opportunities, financial and income needs, friendship and socialization needs, transportation needs, health and medical needs, and legal/advocacy needs.

Historical Background

Transitional planning, for youth with disabilities, was first mandated by federal legislation in 1990 with the passing of PL 101-476, IDEA, 1990. The reauthorization of IDEA in 1997 added new components to the formal process of transitional services. In 1997, the Individuals with Disabilities Education Act was amended to strengthen accountability and academic expectations for children with disabilities across the United States. In particular, transition services were more clearly outlined and defined as a coordinated set of activities for a student, with a disability, that (a) is designed within an outcome oriented process that promotes movement from school to post-school activities, including postsecondary education, vocational training, integrated employment (including supported employment), continuing and adult education, adult services, independent living, or community participation; (b) is based on the student's needs, taking into account the student's preferences and interests; (c) includes instruction, related services, community experiences, the development of employment and other post-school objectives, and, when appropriate, acquisition of daily living skills and functional vocational evaluation (Section 602).

IDEA '97 states:

- (vii)(I) beginning at age 14, and updated annually, a statement of the transition service needs of the

child...that focuses on the child's courses of study (such as participation in advanced-placement courses of a vocational education program)' (ii) beginning at age 16 (or younger, if determined appropriate by the EP Team), a statement of needed transition services for the child, including when appropriate, a statement of the interagency responsibilities or any needed linkages; (III) beginning at least one year before the child reaches the age of majority under State law, a statement that the child has been informed of his or her rights under this title that will transfer to the child...on reaching the age of majority under 615(m) Section 614(d).

This legislature advised that transition services be addressed in the IEP at age 14; therefore, at age 14, the IEP becomes an Individualized Transition Plan or ITP.

Current Knowledge

In preparation for the development of this ITP, transitional assessment must already be completed.

This was a long range plan for what students will do in their remaining years in school as well as what they will do when they exit school. This plan identifies the supports they will receive in school as well as other nonschool supports. In this statement, interagency supports can be identified as well as activities to address transitional needs within home and community environments.

IDEA 2004 changed the age of transitional planning from age 14 to age 16. This is an interesting change considering that in 1990, the U.-S. House of Representatives Committee who reported on the authorization of 1990 stated:

age 16 may be too late for many students, particularly those at risk for dropping out of school and those with the most severe disabilities. Even for those students who stay in school until age 18, many will need more than two years of transitional services. Students with disabilities are dropping out of school before age 16, feeling that the educational system has little to offer them. Initiating services at a younger age will be critical.

(U.S. House of Representatives Report No. 101-554, 10, 1990) States however, may decide to continue mandating transitional services at age 14.

This model is fairly straightforward, including three major components (Storms et al. 2000). First, every student and his or her family should be advised to (1) think about post-high-school goals and (2) develop a plan including supports and services needed to accomplish these goals. (3) The linkages to post-high-school services, supports, and programs need to be identified and made before the student exits high school. The provisions on transition (IDEA 2004) indicate that transitional services should be based on students' *strengths*, needs, interests, and preferences. The addition of "strengths" indicates that transition assessment summary should not just identify areas of need (deficits) but should also provide a description of student's knowledge and skills relative to functioning in post-school environments as well as the planning that has been accomplished.

Individuals with Disabilities Education Act (IDEA)

Jacqueline Kelleher

Education, Sacred Heart University Isabelle
Farrington School of Education, Southern
Connecticut State University, Fairfield, CT, USA

Definition

The Individuals with Disabilities Education Act (IDEA) is an amended version of a landmark federal law passed in 1975 called the Education for All Handicapped Children Act or Public Law 94–142. The IDEA, which has been in place since 1990 with key amendments and revisions occurring as part of reauthorization proceedings in 1997 and 2004, ensures that children and youth with disabilities are afforded basic rights such as a free appropriate public education (FAPE) in the least restrictive environment (LRE), regardless of the nature or severity of the disability. There are four parts to the IDEA that pertain to the following: general provisions under the law (Part A), eligible children ages 3–21 (Part B) and ages 0–2 (Part C), and technical assistance available to state and local education agencies (Part D). In addition to FAPE in the LRE, the IDEA requirements are in place to ensure each state and locality makes provisions regarding identification, due process, individualized education programs (IEPs) or individualized family services plans (IFSPs), nondiscriminatory evaluations, confidentiality, personnel development, and other basic rights established for eligible children and youth with disabilities. The IDEA is known as funding legislation. Part B of the IDEA provides funds to state educational agencies (SEAs) and local educational agencies (LEAs) to help them ensure that children with disabilities, including children aged 3 through 5, have access to a free appropriate public education to meet each child's unique needs and prepare him or her for further education, employment, and independent living. Part C of the IDEA provides funds to each state-led agency

designated by the governor to implement state-wide systems of coordinated, comprehensive, multidisciplinary interagency programs and make early intervention services available to infants and toddlers with disabilities and their families. While all states participate in IDEA mandates and requirements, the law applies only to those agencies receiving federal funds; for example, an independent or private school not accepting federal dollars may be exempt from IDEA requirements and regulations; however, this does not exempt them from civil rights legislation in place for individuals with disabilities such as the Americans with Disabilities Act (ADA) or Section 504 of the Rehabilitation Act.

Historical Background

As one effort to address years of widespread discrimination against individuals with disabilities with respect to access to quality education and educational services, the United States Congress passed Public Law 94–142 in 1975, the Education for All Handicapped Children Act, mandating school services for children with disabilities. Over time, the law has been amended and revised into its current iteration, the Individuals with Disabilities Education Act or IDEA, renamed in 1990, to reflect its mandates focused on the educational needs of children and youth with disabilities ages birth through the 22nd birthday. Since the renaming of PL 94–142, the IDEA has added protections and regulations with each reauthorization such as the development and review at least annually of an individualized education program (IEP) for eligible children ages 3–21 or an individualized family services plan (IFSP) for infants and toddlers. Families have been specifically named and included in the IDEA as full participants in the decision-making process with legal protections written into the law to ensure parent and student rights are not violated. As part of its most recent modifications in 2004, the IDEA now includes regulations for special services including transition services and protections addressing disciplinary issues for eligible children under the Act.

Current Knowledge

The Individuals with Disabilities Education Act (IDEA) is the primary federal program that authorizes state and local aid for special education and related services for eligible children with disabilities. According to IDEA, the term “children with disabilities” means those children evaluated in accordance with Regs. Secs. 300.530-300.534 as having mental retardation, hearing impairments including deafness, speech or language impairments, visual impairments including blindness, serious emotional disturbance, orthopedic impairments, autism, traumatic brain injury, other health impairments, specific learning disabilities, deaf blindness, or multiple disabilities and who because of those impairments need special education and related services. On December 3, 2004, President Bush signed the Individuals with Disabilities Education Improvement Act (P.L. 108–446), a major reauthorization and revision of IDEA. The IDEA 2004 and its federal statutes and regulations currently serve millions of eligible children and youth with disabilities under its provisions. With a commitment to ensuring the provision of a free appropriate public education for those found eligible for a special education and related services, past and current issues for states and citizens concern funding. The most significant funding stream to state education agencies (SEAs), who in turn disseminate funds to local education agencies (LEAs), is that authorized by Part B, with a majority of funds allocated toward Part B initiatives. Currently, Congress has set a maximum target for the federal contribution to special education spending equal to 40% of the estimated excess cost of educating children with disabilities. Thus, if the program were “fully funded,” the states would receive their maximum grants, calculated at 40% of the national average per pupil expenditure times the number of children with disabilities served in the school year 2004–2005, adjusted for population changes. Under the act, the count of children with disabilities cannot exceed 12% of the state’s total school population. Current knowledge regarding the funding formula and resource allocations to each SEA is that there is a shortfall in IDEA funding, with costs not reimbursed or absorbed by the federal

government assumed by the states and local school districts. The American Recovery and Reinvestment Act of 2009 (ARRA) appropriated new funding for programs under Parts B and C of the Individuals with Disabilities Education Act (IDEA). The IDEA 2004, which is currently up for reauthorization as of this writing, is monitored and enforced at the federal level by the Office of Special Education Programs (OSEP).

Future Directions

The Individuals with Disabilities Education (IDEA) Act of 2004 is under review for reauthorization.

Description

The Infant Toddler Checklist (ITC) is a one page developmental screener that asks about early

social communication development. It has been normed on over 2000 infants and toddlers and can be used with children between 6 and 24 months of age.

Historical Background

Wetherby and colleagues (Wetherby et al. 2008; Wetherby et al. 2004) developed an early screening tool that can be used from 6 to 24 months of age – the Infant Toddler Checklist (ITC). The ITC is a broader developmental screen that successfully identifies children with developmental, in particular language and communication, delays as well as children with an autism spectrum disorder (ASD). The ITC is one component of the suite of early social communication assessments, known as the Communication and Symbolic Behavior Scales-Developmental Profile (CSBS-DP: Wetherby and Prizant 2002). The ITC can be downloaded for free at: <http://firstwords.fsu.edu/toddlerChecklist.html> and is currently available in English, Spanish, Slovenian, Chinese, and German. The ITC consists of 24 questions about early social communication behavior (e.g., “Does your child let you know when he/she needs help or wants an object out of reach?”; “When you call your child’s name, does he/she respond by looking or turning toward you?”). Unusually for early ASD screening instruments the ITC has norms developed from a reference sample of over 2000 infants and toddlers (Wetherby and Prizant 2002).

Psychometric Data

In an initial study Wetherby et al. (2004) screened 3021 children from a population sample between 6 and 24 months of age. Low scorers (<10th centile) and a random subsample scoring within the typical range were seen during the second year of life for face-to-face behavioral assessments and again around their third birthday. Eighteen children received a diagnosis of ASD and 18 a diagnosis of developmental delay (DD). Sensitivity of the ITC for identifying ASD was 94.4% (17/18)

and for identifying DD was 83.3% (15/18). Thus, from this initial study the instrument parameters of the ITC for identifying toddlers with ASD and DD appeared highly promising.

In their most recent work, Wetherby and colleagues have shown that it is possible to prospectively identify toward the end of the first year of life children who will go on to have a diagnosis of an ASD (Wetherby et al. 2008). From a larger sample of 5385 were screened on multiple occasions (every 3 months) some from as young as 6 months. The authors describe how children who fell below various 10% centile cut-points on the social composite, symbolic composite, and speech composite were invited for face-to-face assessments. In all, nearly 1000 children were assessed ($N = 978$). The positive predictive value (PPV) of the ITC parental checklist for identifying children with delayed development rose from 42.9% on those screened at 6–8 months of age to 79.0% in those screened at 21–24 months of age. In terms of identifying children with an ASD, 56 of the 60 children with an ASD were “flagged” as screen positive on the ITC at first administration, including some from assessments between 9 and 14 months of age. The instrument properties of the ITC, in common with many other ASD screens will require further follow-up of these sample to determine whether there have been other children who go on to develop an ASD who were picked up by the screen.

Clinical Uses

However, this series of studies on the ITC is one of the most developed screening studies undertaken so far. It shows good promise in identifying children with ASD and other developmental/communication difficulties. It also has three notable features. First, it was developed as a surveillance tool. Surveillance involves a parent-professional partnership that takes a broader look at developmental and behavioral skills and progress over time. It combines the observations of parents with the developmental knowledge of the professional and the deployment of specific tests.

Second, it was developed as part of a suite of assessments from the ITC parental checklist to the direct assessment the CSBS-DP. Finally, it was intended to capture not only ASD but also children with other developmental and communication delays. Within general child health settings this holds promise as a broader screener that clinicians can use to identify children who warrant assessment.

Blitz-Nick-Salaam Krämpfe; Infantile myoclonic epilepsy; Infantile spasms syndrome; Massive infantile spasms; Myoclonic spasms of infancy; West syndrome

Infantile spasms or West syndrome consists of infantile spasms, hypsarrhythmia, and mental retardation. The spasms are usually resistant to conventional antiepileptic drugs. The typical syndrome has its onset between 3 and 7 months of age and seldom after age of 1 year.

Now, however, it is known that there is a great variability of the features. Any feature of this classical triad may be missing.

Categorization

According to the up-to-date International League against Epilepsy (ILAE 2001) Classification, West syndrome is an epileptic syndrome consisting of clinical spasms usually in clusters with epileptiform EEG, with onset usually less than 2 years of age. West syndrome is an epileptic encephalopathy where cognitive, motor and/or sensory functions are altered by the epilepsy.

Two main groups of the syndrome are recognized: symptomatic and cryptogenic. In *symptomatic* (80%) spasms, there is a history of pre-, peri-, or postnatal damage or disease, and the predisposing etiology can be identified. In *cryptogenic* (15–20%) spasms, there is normal development prior to the onset of the spasms, and no known cause is revealed by clinical and neuroradiological examinations. This group has a probably symptomatic etiology, but underlying causes remain hidden. The rare idiopathic (5%)

refers to a pure functional cerebral dysfunction. Genetic factors play an important role.

The terms idiopathic and cryptogenic have been used as synonyms of each other in some studies. Classification depends heavily on the extent of the investigations performed.

Epidemiology

The incidence of West syndrome has been estimated to vary from 1.6 to 4.3 per 10,000 live births.

Natural History, Prognostic Factors, Outcomes

Infantile spasms are a time-limited disorder, with spasms usually ceasing after a few (3–4) years, even when treatment is not successful. Spontaneous remission rate is 25% within 1 year of onset. However, most patients continue to have significant developmental delay.

The mortality in the follow-up of 25–35 years is 33–35%.

Prognostic Factors

The primary goals of the treatment of infantile spasms are cessation of the spasms and improvement of the mental developmental outcome.

Factors associated with a favorable outcome (Riikonen 2009) include:

1. No other seizures before onset of infantile spasms
2. Absence of atypical spasms, partial seizures, and asymmetric EEG abnormalities
3. Age of onset between 4 and 9 months

The above-mentioned factors are also associated with cryptogenic etiology.

4. Early and sustained response to treatment
5. Short duration of hypsarrhythmia

In the recent prospective UK study (Lux et al. 2005), the developmental outcome of children treated with hormonal (n = 55) or vigabatrin (VGB) (n = 52) therapy was compared at age 14 months. In infants with no identified

underlying etiology ($n = 46$), the mean Vineland Adaptive Behavioral Scale scores were higher in those allocated to hormone treatment than those allocated to VGB treatment. This difference was even greater at the age of 4 years (median difference 14 scores). Hormone treatment therefore seems to be the better first treatment (Darke et al. 2010).

Outcomes

Short Term

If the etiology is cryptogenic the spasms will cease in 80%. If the etiology seems to be symptomatic the spasms will cease in 50%. However, at 3–4 months after starting treatment only 40–44% are seizure-free.

Long Term

We know the long-term outcome after corticotrophin (ACTH) therapy but not after VGB therapy. In Finland, 214 children were followed up for 25–35 years or until death (Riikonen 2001). This study assessed the death rate, autopsy findings, intellectual outcome using standardized psychometric tests, education, occupations, psychiatric disorders, and occurrence of epilepsy and follow-up EEG. The patients had been participants in a prospective study conducted in 1960s, and follow-up was obtained in 100% of the cases. The patients had been on the following treatments: large doses of ACTH (120 IU = 0.12 mg/day) ($N = 54$) or lower doses (20–40 IU = 0.02–0.04 mg/day) ($N = 97$). Large doses given for a relatively short period of 6 weeks were not more effective than the smaller doses. The long-term intellectual outcome was better in children treated with lower doses than with larger doses.

One third died, of which a third died before the age of 3 years. Normal or mildly abnormal intelligence was present in a quarter. They went to normal school or school for educationally impaired children, a quarter to training school, and the rest were uneducable. Twenty-five percent had employment ranging from professional to manual labor. Ten were married. Five had children, altogether ten healthy children. A quarter was

institutionalized. A third was seizure-free, a fifth had daily seizures, and the rest had less frequent seizures. EEG was normal or slightly abnormal in 22% of the cases at the last examination. Focal abnormalities were seen in 37%. Focal abnormalities were equally frequent in patients with normal and patients with less favorable outcome. In several studies, investigators have failed to find any correlation between various EEG features and long-term outcome.

Kumagai et al. (2001) evaluated the long-term prognosis of 120 patients in Japan at the mean age of 25 years.

This cohort suggested that 60% had a reasonable quality of life (such as walking, communication, eating, dressing, and toileting).

Autism and Infantile Spasms

Epidemiology

Psychiatric disorders following infantile spasm have received relatively little attention in the literature. In Finland, a systematic search for autism was made for 192 children with infantile spasms and 24 patients had infantile autism (Riikonen and Amnell 1981). In a population-based study in a cohort with seizures in the first year of life (95 children), infantile spasms predicted a high risk for autism spectrum disorders (Saemundsen et al. 2008).

Etiology and Pathogenesis

Epilepsy and/or epileptic EEG abnormalities are frequently associated with autistic disorders in children, but this does not necessarily imply that they are the cause. Nevertheless, there are different etiologies where a direct relationship between early epilepsies and autism may be suspected. The direct role of epilepsy can only be evaluated in longitudinal studies. It seems probable that the later psychiatric manifestation is connected with the same brain lesion which had earlier caused the infantile spasms. In the majority of cases, specific underlying causes cannot be identified. However, a number of factors are being investigated including infectious, metabolic, genetic, and environmental causes (Table 1). Large numbers of tests in the absence of a specific clinical indication are

Infantile Spasms/West Syndrome, Table 1 Etiological investigations of infantile spasms

Comprehensive history:	Heritable disorders, pre- and perinatal events
Clinical examination:	Signs of tuberous sclerosis
Funduscopy:	Phacomias, intrauterine infections, metabolic diseases

Urine:	Organic acids
Serum:	Amino acids
Chromosomal abnormalities:	If structural brain abnormalities, dysmorphic features
Pyridoxin (phosphate) 100 mg i.v. to screen pyridoxine-dependent seizures	

wasteful and unlikely to generate useful data for clinical care. The frequency of autism in tuberous sclerosis is estimated as high as 8–14% among the subgroup of autistic individuals with a seizure disorder. Autistic behavior can often be seen (in 58%) in tuberous sclerosis and infantile spasms (Hunt and Dennis 1987).

The presence of autism may arise if the tuberous sclerosis mutation occurs at critical stages of neural development of brain regions critical in the development of autism. Early epilepsy and functional deficits associated with the anatomical lesions in the temporal lobes may be associated with autism. There is emerging evidence that early onset electrophysiological disturbances within temporal lobes (and perhaps other locations) have a deleterious effect on the development and establishment of key social cognitive representations concerned with processing social information. Temporal abnormalities were found in 70% of the patients with autism (Riikonen and Amnell 1981). This corresponds with the positron emission tomography (PET) studies where 70% of the patients with infantile spasms and autism have bitemporal hypometabolism (Fig. 3). Location of tubers in the temporal lobes, however, does not seem not be a sufficient risk factor for development of autism. Very recently, it has been shown that seizure

activity in the left temporal lobe is a risk factor for autism spectrum disorders in tuberous sclerosis (Numis et al. 2011).

Differential Diagnosis

Severe sensory deficits may make false interpretation of the behavior of the child. Majority of children with autistic behavior are mentally retarded. Retarded children have a tendency to develop autistic behavior because of their cognitive and perceptual deficits and because of environmental deprivation during long-term stays in hospitals and institutions. It must be emphasized, however, that autism and mental retardation are far from synonymous.

Treatment

Behavioral treatments remain the cornerstone of management. Early diagnosis of autism will allow for earlier treatment and better outcome.

Clinical Expression and Pathophysiology

Clinical Expression

Spasms

The spasms may be flexor, extensor, or, most commonly, mixed spasms. One child can have various types of the spasms. Spasms occur in clusters. The presence of subtle spasms, asymmetric or asynchronous spasms, and focal signs suggests a symptomatic etiology and are associated with unfavorable outcome in the long term. A number of investigators have documented the coexistence of partial seizures occurring in patients with infantile spasms. They are common in drowsiness and especially on arousal or soon thereafter. A vast number of spasms are missed by parents when compared with those seen in video monitoring.

The diagnosis of the spasms is easy when they are typical. However, the spasms are often misinterpreted and considered to be colic, startle responses, or normal infant behavior. Repetitive, stereotyped characterization of any movements in infancy should arouse the suspicion of infantile spasms and lead to an immediate EEG examination.

Electroencephalogram (EEG)

Hypsarrhythmia consists of a pattern of irregular, diffuse, asymmetric, high-voltage slow waves interspersed with sharp waves and spikes, distributed randomly throughout scalp recordings (total chaotic disorganization of cortical electrogenesis) (Fig. 1). The term “modified hypsarrhythmia” (occurring in about 40%) is used if there is some preservation of background rhythm, synchronous bursts of generalized spike-wave activity, significant asymmetry, or burst suppression of tracing. A constant focus of abnormal discharges may also precede, accompany, or follow hypsarrhythmia. Multifocal spikes may also evolve into hypsarrhythmia if there is a long delay before treatment of spasms. A transition from typical hypsarrhythmia to a pattern of multifocal spike activity during treatment with vigabatrin (VGB) is observed in a number of patients. Persistence of multifocality means that there are always spasms which may be subtle.

The most common ictal pattern associated with symmetric spasms is a generalized slow wave, usually followed by attenuation of background

activity (Fig. 2). The initial diagnosis of infantile spasms may require video-EEG studies in infants with symptomatic etiology who may show only subtle spasms. Constantly normal tracing, including sleep recording, rules out the diagnosis of infantile spasms. EEG should always include waking and sleeping states.

Autistic-like Behavior of an Infant Sometimes the infant ceases to take interest in his surroundings, and blindness is suspected. This functional amaurosis is seen in association with missing or grossly abnormal patterns of visually evoked potentials and probably corresponds to perfusion defects involving the parieto-occipital areas. In addition, behavioral regression (autistic-like behavior) of an infant less than 1 year of age should lead to an EEG examination, in which hypsarrhythmia may reveal the cause of regression.

Pathophysiology of Infantile Spasms
Problems with modulation of neurotransmitters at a specific period of brain maturation are believed

Infantile Spasms/West Syndrome, Fig. 1 Typical hypsarrhythmia

Infantile Spasms/West Syndrome,

Fig. 2 Hypsarrhythmia disappears between the spasms

to be fundamental to the development of infantile spasms. The latter usually appears when at the age which corresponds to the critical period of maximal brain development and age and is supported as follows:

Infantile spasms and hypsarrhythmia disappears spontaneously with age of high corticotrophin-releasing factor (CRF) abundance. Glucocorticoids have an accelerating effect on some physiological events.

The molecular mechanisms which lead to the long-term consequences of infantile spasms are poorly understood. It has been suggested that early stress (injury or insult) during a critical pre- and perinatal period activates proconvulsant stress mechanisms, increasing CRF synthesis and activity, with resultant long-term effects (Brunson et al. 2001). Insults or stress in early life may affect the synthesis of insulin-like growth factor-1, which might play a role in disturbance of synaptogenesis and reduction of certain cognitive functions (Riikonen 2010). The existence of a latent period also raises the possibility of preventive intervention.

Evaluation and Differential Diagnosis

Evaluation

The infantile spasms clinical evaluation begins with the history and physical examination of the

patient. Evaluating the EEG is critical for the diagnosis of infantile spasms and for patient management. It is recommended that an EEG evaluation be conducted as soon as possible following the identification of spasms.

Careful search for etiological factors should be done in every case to formulate a more accurate prognosis and establishing the need for genetic counseling. Within symptomatic group, the etiologies for infantile spasms have traditionally been divided into pre-, peri-, and postnatal causes. Most studies identify prenatal etiologies as the most common, accounting almost 50% of symptomatic cases.

More than 200 potential etiological factors for infantile spasms have been reported. However, they are not necessarily causally related. History and physical examination alone may identify the majority of symptomatic spasms. MRI is the most important diagnostic tool. Seventy-percent will have established etiological diagnosis without need to conduct extensive testing (Table 1). MRI may need to be repeated after 18 months to 2 years after myelination of the brain is more complete as early scans may miss gray matter abnormalities. Common abnormalities revealed by MRI are focal cortical dysplasias, thinning of the corpus callosum and delayed myelination. Inborn errors of metabolism are a rare but significant cause of infantile spasms. Often there have been preceding seizure types. Rarely, West

Infantile Spasms/West Syndrome, Table 2 Genetic causes of infantile spasms

Tuberous sclerosis	Aicardi syndrome
	Miller Dieker syndrome
	Progressive encephalopathy-hypsarrhythmia-optic atrophy (PEHO) syndrome
	Down syndrome
X-linked:	ARX aristaless-related homeobox gene
	CDKL5/STK9 kinase gene
	MECP2
	STXBP1

syndrome occurs with single-gene metabolic disorders. While each of the genetic mutations is rare, collectively they comprise an increasing proportion of infantile spasms etiology (Table 2). Tuberous sclerosis is the most important genetically defined disease.

Differential Diagnosis

Syndromes closely related to West’s syndrome include infantile epileptic encephalopathy and early myoclonic encephalopathy. Both are very rare syndromes. They are characterized by onset before 3 months of age and a severe course, with lack of psychomotor development. Response to ACTH is poor. Both syndromes have a burst-suppression pattern in EEG. West’s syndrome may be replaced in a quarter of patients by another severe epilepsy syndrome, Lennox-Gastaut syndrome, which is an important differential diagnosis for patients more than 1 year of age. There is a transition between the four syndromes.

Treatment

The delayed psychomotor development that characterizes epileptic encephalopathy justifies vigorous treatment.

Many studies have shown that the cognitive outcome is better when the lead time to treatment is short (Riikonen 2009).

Infantile Spasms/West Syndrome, Table 3 Alternative therapies in the treatment of infantile spasms: pooled data from different studies

Therapy	Number of patients	Response rate (%)
ACTH	476	59
Prednisone	26	31
High-dose prednisone	30	70
Vigabatrin	1,026	37
High-dose valproate	41	54
Nitrazepam	27	52
Pyridoxine	118	13
Zonisamide	119	27
Lamotrigine	30	29
Topiramate	35	29
Sultiame	17	35
Ketogenic diet	104	37

Short-Term Effects

Infantile spasms are usually resistant to conventional antiepileptic drugs. Most studies are dealing only with short-term effects of the drugs. The outcome measures should be the following: cessation of the spasms, resolution of hypsarrhythmia, relapse rate, absence of epilepsy and epileptiform EEG, cognition and behavior. More than 150 trials have carried out in the treatment of infantile spasms (Table 3). Steroids and vigabatrin are now the first-line drugs for infantile spasms. In a large data-based critical review of American Academy of Neurology and Child Neurology Society, nine ACTH prospective studies were analyzed (Mackay et al. 2004). It was concluded that there is insufficient data to recommend the optimal dosage and duration of ACTH. “ACTH is probably effective and vigabatrin possibly effective for short-term treatment of infantile spasms and possibly effective for children with tuberous sclerosis.”

ACTH or Oral Steroids?

In a small prospective, randomized study, the efficacy of high-dose ACTH (150 IU/m² for 2 weeks) was better than that of prednisone (2 mg/kg for 2 weeks) (Baram et al. 1996) but a

small prospective double-blind study found otherwise.

In a new prospective study from the United Kingdom (UK) (Lux et al. 2004), 107 patients were randomized to tetracosactide (synthetic ACTH) 0.5 mg/day (40 IU) on alternate days and prednisolone 40 mg/day. The response rates were 76% and 70%, respectively. The difference was not significant on day 14 of treatment. Tuberous sclerosis (TS) was excluded in this study because VGB was considered to be the drug of choice in TS (Hancock et al. 2008).

Although ACTH will downregulate CRF via melanotropic receptors and decrease excitability in the limbic system (Brunson et al. 2001), oral steroids themselves, which do not have down-regulating effects of CRF, have clear clinical influences. ACTH and oral steroids might accelerate physiological events during critical stages of brain development through action as a trophic hormone. The reasons for the efficacies of ACTH and steroids require further elucidation.

Dose of ACTH?

The doses vary in different countries: Japan 0.1 mg/day, Finland 0.25 mg/day, and USA 0.8 mg/day (80 IU).

It is not clear why infants in the USA would need considerably larger doses than in Japan.

Corticotrophin, so-called natural ACTH, acts for 12–18 h. Its synthetic derivate, tetracosactide, lasts for 24–48 h. The international units of ACTH and tetracosactide are believed to be equivalent: corticotrophin 80–100 IU is equivalent to tetracosactide 1 mg. Tetracosactide is used on alternate days because of its prolonged action. The relatively serious side effects of tetracosactide are probably due to its prolonged action. Natural ACTH (“Achter”) is not available in Europe, and synthetic ACTH (“Synachten”), not in USA. The first drug is much more expensive than the latter.

In a small blind prospective study by Hrachovy et al. 1994, high doses (150 IU/m²) given for 3 weeks were not more effective than lower doses of ACTH (20–39 IU/day) given for 2–6 weeks or hydrocortisone given for shorter periods. In a Finnish studies, there were no difference in response rate or relapse rate comparing low dose

(20–40 IU/day) and high dose (100 IU/day). The long-term cognitive outcome was better with low dose regimen.

Recently, in a large US review (Pellock et al. 2010) it was concluded that ACTH is the preferred therapy, but the optimal dose is still unknown.

Steroids or Vigabatrin?

Vigabatrin has gained popularity because of its ease of use and its efficacy. In Europe, opinions are divided with regard to vigabatrin as initial treatment. In USA, vigabatrin was approved by FDA in 2009, and both drugs are now the first-line therapies (Pellock et al. 2010). Compared to vigabatrin, more patients will respond with ACTH (Vigevano and Cilio 1997; Lux et al. 2004), with tuberous sclerosis excluded in the latter study. Depending on the study, after 2 weeks of therapy, patients treated with vigabatrin were seizure-free in 26% (Granström et al. 1999), 23% (Elterman et al. 2001), and 54% (Lux et al. 2004) of cases. However, at 3 months, the number of seizure-free patients increased to 60–65% in the two former studies. These data suggest that the response with vigabatrin comes later than with ACTH. After 14 months of treatment, there was no difference in seizure frequency between patients treated with vigabatrin and those treated with oral hormones (Lux et al. 2005). The dose of vigabatrin has ranged from 40 to 120, usually 40–60 mg/kg/day, given in two daily doses.

After pooling the data of 8 separate prospective and retrospective studies, vigabatrin was effective in 44% of 478 patients. In the pooled data of 9 separate prospective and retrospective studies, ACTH was effective in 59% of 476 patients. In the recent UK study (which excluded TS patients), the cessation of the spasms was more likely with hormonal treatment. VGB was effective for spasms in 54% and hormonal treatment 70% on day 14.

Tuberous Sclerosis

VGB is used in tuberous sclerosis (Hancock et al. 2008). The response rate to VGB and ACTH are similar, more than 70%. However, relapse rates are high after both drug trials. Because the use of

ACTH is always given for a specified period and VGB for an indefinite period, VGB is a better choice.

Relapses

The hormonal treatment may be stopped after only 1 month and vigabatrin after 3 months (Willimore et al. 2009; Pellock et al. 2010).

The relapse rate after ACTH treatment is estimated to be 15–24%. There is not enough information of relapse rate after VGB therapy.

The numbers of patients who were seizure-free at 3–4 months after ACTH or VGB treatment are very similar (42–44%). In the recent UK study, the number of patients who were spasm-free at 14 months was very similar.

A new course of ACTH is effective in two thirds of the cases. In refractory cases valproate, nitrazepam, topiramate, or vigabatrin are recommended. Ketogenic diet or surgery should also be considered.

Side Effects

Both drugs have severe side effects. The side effects of ACTH are infections, arterial hypertension, and adrenal hypofunction after therapy. For infants with a history of frequent respiratory infections, prophylactic trimetoprim-sulfaxazole therapy might be recommended.

Hypertension should be monitored and treated. In hypertensive patients, the heart should be studied by ultrasound to recognize hypertrophic cardiomyopathy. Hydrocortisone substitution should be given after ACTH therapy and continued until the adrenal axis has normalized.

In Finland, the therapy is given at minimal effective dose and for the minimal effective time (Table 4). With such treatment, no serious side effects were found. The side effects of ACTH might be severe, but they are all treatable and reversible.

A serious concern in regard of concentric visual field defects (VFDs) has arisen in relation to the use of VGB. The visual field defects it causes seem to be permanent. One recent systematic review (Maguire et al. 2010) showed that VFDs occur in 40% in adults and in 34% in children. The earliest sustained onset of the

VGB-induced retinal defect is at 3 months (Willimore et al. 2009). VFD defects are sufficient to prevent a person from driving. There are also concerns with children who might have a poor underlying function as a part of their overall neurological disabilities.

In 2009, the U.S. Food and Drug Administration approved vigabatrin “if the patients have periodic ophtalmological evaluations at initiation of therapy, at every 3 months while taking VGB as well as 3–6 months after cessation of treatment”. However, accurate assessment of visual field changes in infants is challenging and no consensus exists on a protocol for visual evaluation for infants. Transient changes in basal ganglia, thalamus, brainstem, and dentate nucleus have been recently shown.

The other regimens used in the treatment are seen in Tables 5 and 6.

Infantile Spasms/West Syndrome, Table 4 Regimen 1 for use of ACTH or vigabatrin for infantile spasms in Finland (Finnish Guidelines for Childhood epilepsy 2007; Riikonen 2009)

After a short trial with pyridoxine, ACTH or vigabatrin are the first-line drugs
Start with tetracosactide 0.03 mg/kg or 0.5 mg on alternate days for 2 weeks and then tapering the dose during the next 2 weeks, or alternatively doubling the dose to 0.06 mg/kg for 2 weeks and then tapering
Start with VGB 40 mg/kg/day and continue up to 10 days. In responsive cases, use up to 3 months
In nonresponsive cases, switch to ACTH after 10 days
Use VGB as the first drug for tuberous sclerosis
Use ACTH as the first drug for cryptogenic cases

Infantile Spasms/West Syndrome, Table 5 Regimen 3 U.S. consensus report (14 centers) (Pellock et al. 2010)

Short-term treatment with a first-line treatment with maximum effective dose for 2 weeks
EEG evaluation of effectiveness (“all-or-none” response, presence or absence of infantile spasms, hypsarrhythmia, or epileptiform electroencephalography discharges)
Prompt treatment modification
No consensus of the first-line drug
No consensus on initial treatment dosage

Ketogenic Diet

The ketogenic diet may be an option in drug-resistant epilepsy as an adjunct to pharmacological therapy or as alternative when first-line treatments (ACTH and VGB) fail (Hong et al. 2010).

Surgery

Surgery may be the treatment of choice in a small number of patients, refractory to medical treatment (but no evidence of metabolic or degenerative disorders), and in which localized lesions are present (Fig. 3). The authors recommend that surgical intervention should be considered early in the medically refractory cases prior to the onset of epileptic encephalopathy. When a single lesion is present on the MRI and there is a good correlation with EEG localization, surgical treatment is quite favorable in terms of both seizure control and cognitive development. Positron emission tomography (PET) complements MRI by defining

the full extent of lesion and evaluating the integrity of the full lesion. PET abnormalities may also guide placement of intracranial electrodes. Development of newer more specific PET probes for epilepsy has led to improved and more accurate localization of seizure foci. Recent advances in pediatric epilepsy surgery include resection of multiple tubers in children with tuberous sclerosis. Thus, this development should ultimately improve the outcome of epilepsy surgery in West syndrome.

Conclusion

In West syndrome, many advances have been achieved:

- Identification is more precise, using video and polygraphic recordings.
- More accurate etiological diagnoses can be made by clinical, neuroimaging, genetic, and pathologic methods.
- Hormonal therapy is the most effective therapy in the short term and might bring better cognitive outcome in patients with cryptogenic spasms.

Infantile Spasms/West Syndrome, Table 6 Regimen 4 Japan (Fukuyama 2010)

Vitamin B 20–40 mg/kg/day for 2 (?)weeks
SyntheticACTH 0.0125 mg/kg/day for 2 weeks and tapering

Infantile Spasms/West Syndrome,

Fig. 3 Infantile spasms: metabolic patterns in 250 cryptogenic cases. Note the bitemporal hypometabolism in a case with autism (Children’s Hospital of Michigan, Wayne State University, with courtesy of Professor Harry Chugani, presented in Infantile Spasms Progress in Epileptic Spasms and West syndrome Congress in Rome 1997)

- Cognitive development is not possible if hypsarrhythmia persist. Short lead time to treatment is essential. Effective treatment for infantile spasms should be “all-or-none” response.
- Side effects of the main drugs, ACTH and VGB, are better known.
- In some patients, surgical approach seems of benefit in achieving seizure control.

On the other hand,

- There is lack of consensus on the drug of first choice
- Frequency of visual field defects in children treated with VGB should be studied in addition to the long-term outcome in general

Advances in our understanding of brain maturation, etiologies mechanisms, and genetics underlying West syndrome may facilitate more effective pharmacological interventions.

Infants with Autism

Grace W. Gengoux
Child and Adolescent Psychiatry, Stanford
University School of Medicine, Lucile Packard
Children's Hospital, Stanford, CA, USA

Definition

Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder with initial onset of symptoms early in life. When early infantile

autism was first described by Leo Kanner (1943), the symptoms were assumed to be present from birth. Though the exact etiology of ASD is still unknown, and some children may show a regression or plateau in development, it is still believed that most children with ASD are born with the disorder. However, much remains to be learned about the characteristics of autism in infancy.

ASD is a highly heritable complex genetic disorder which may actually have multiple etiologies and likely involves susceptibility genes as well as epigenetic factors which are not yet well understood (Abrahams and Geschwind 2008). In the absence of any biomarker, ASD is defined by its behavioral profile. Though historically most children with ASD have been diagnosed and treated in the preschool and school-age years, research evidence indicates that the symptoms of ASD emerge in the first and second year of life. Infants with ASD may display emerging signs of the social communication deficits inherent in autism including limited eye contact, reciprocal social smiling, response to name, babbling, communicative gestures, and functional and symbolic play. Stereotyped motor movements and preoccupation with parts of objects may present in the first or second year of life. In the first year, late onset of social smiling and poor responsivity to speech may trigger initial parent concerns. Research indicates that early diagnosis is relatively stable, and early initiation of treatment improves prognosis.

Much of what is currently known about the early development of children with ASD has been learned from prospective studies of infant siblings of children with ASD. These siblings are at increased genetic risk of developing ASD, as well as other developmental delays. As these babies are followed prospectively by experts, their behavior can be analyzed for the earliest signs of an atypical developmental trajectory.

Historical Background

From the first reports by Leo Kanner (1943), autism was presumed to be a congenital disorder with origins in infancy, and research to date has generally supported this notion. The social

communication behaviors which are disrupted in ASD have their origins in the first year of life for typically developing infants, suggesting that the pathogenic processes which give rise to ASD are likely present from a very early age. For example, within the first weeks of life, typically developing infants prefer social stimuli such as faces and speech sounds. By 4 to 6 months of age, infants engage in contingent dyadic interactions with caregivers, and toward the end of the first year and beginning of the second year, infants show emerging capacity for triadic social interaction in the form of joint attention.

However, until recently, ASD was not commonly diagnosed before the preschool years. Therefore, historically, the majority of information about the onset and early progression of autism symptoms came from retrospective parent reports. This early research indicated that up to half of parents of children with ASD recall concerns during the first year of life (De Giacomo and Fombonne 1998; Volkmar et al. 1985), and most parents (80–90%) recall concerns prior to the second birthday (Baghdadli et al. 2003; Chawarska et al. 2007).

The growing use of home video equipment by families to document child development and special occasions at home allowed researchers to retrospectively collect and analyze video recordings of children who later were diagnosed with ASD and controls to assess for the presence of autistic traits in infancy. Indeed, analysis of home videos of children later diagnosed with ASD indicated that eye contact, responsiveness to name, socially directed positive affect, and reciprocal social smiling were less frequent in these children than controls at 12 months of age (Adrien et al. 1993; Baranek 1999; Osterling et al. 2002; Werner et al. 2005).

Though these studies were critical in confirming the early emergence of autism symptoms, given the methodological limitations of retrospective methods and the limited degree to which etiologic factors could be examined, researchers began searching for ways to gather prospective information regarding the characteristics of infants with ASD in order to better inform diagnosis and treatment efforts. However, even

with the prevalence of ASD estimated at 1 in 68 children by the Centers for Disease Control and Prevention (Christensen et al. 2016), without identification of a population of infants at increased risk of developing ASD, the cost of obtaining detailed prospective data on a sufficient number of infants who will later develop ASD has been prohibitive. Given that the genetic risk associated with ASD is considered to be high, siblings of children with ASD are at significantly greater risk of developing the condition than children in the general population, with recurrence rates of ASD in siblings estimated as high as 20% (Bolton et al. 1994; Ozonoff et al. 2011). Therefore, if a large group of infant siblings could be followed prospectively, a proportion of them would develop ASD, thus providing a feasible way to learn about the early developmental characteristics which differentiate infants who do and do not develop ASD (Zwaigenbaum et al. 2007). Based on this logic, multiple large-scale prospective studies of infant siblings of children with ASD were initiated with the objective of identifying earlier neurological and behavioral markers and illuminating the etiology of ASD by following children from the first months of life.

Autism Assessment in Infants

Research indicates that diagnosis of ASD can be reliably made by experts at age two (Chawarska et al. 2008) and is relatively stable in early childhood (Chawarska et al. 2009). At present, assessment using the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2; Lord et al. 2012) and the Autism Diagnostic Interview-Revised (ADI-R; Lord et al. 1994) is considered the “gold standard” for diagnosis of ASD within clinical research. The second edition of the ADOS includes a toddler module (ADOS-T) for children 12–30 months of age with minimal speech (Luyster et al. 2009). However, the ADI-R was not developed for use with infants and toddlers; therefore, professionals using the current version must use caution when interpreting scores for children under 3 years of age. Several other measures have been developed for use in screening for

the presence of autism symptoms in toddlers, such as the Modified Checklist for Autism in Toddlers (M-CHAT; Robins et al. 2001) and the Screening Test for Autism in Two-Year-Olds (STAT; Stone et al. 2000). In addition, the Autism Observation Scale for Infants (AOSI; Bryson et al. 2008) was developed for infants under 18 months of age and is used in many studies of very young children at risk for ASD. Researchers have also utilized other measures such as the Alberta Infant Motor Scale (AIMS) to detect early deviations in development in 3- and 6-month-old high-risk infants (Bhat et al. 2012).

Recent studies suggest that diagnosis is occurring closer to 18 months to 2 years of age due to the increasingly prevalent use of prospective screenings and measures designed for infants (Elsabbagh and Johnson 2010; Guinchat et al. 2012; Shen et al. 2013). Early diagnosis of autism is crucial to ensure access to early intervention services and, subsequently, positive outcomes for at-risk infants and children. As such, the American Academy of Pediatrics (AAP) recommends that all 18- and 24-month-olds be screened for early signs of autism (Zwaigenbaum et al. 2013, 2009).

Additionally, biological and genetic tests are being developed to screen for and potentially diagnose autism in young and at-risk infants. For example, using magnetic resonance imaging (MRI) technology in addition to behavioral assessment, Shen et al. (2013) prospectively studied at-risk infants and found that all infants who were later diagnosed with autism had higher volumes of extra-axial fluid in their frontal lobes at 6 to 9 months than infants not at risk. Furthermore, the larger the volume of fluid at 6 months, the more severe the symptoms of autism were at 24 months of age (Shen et al. 2013). While further research is needed before these tools will be ready for clinical application, considerable progress is anticipated.

Current Knowledge

Existing research on autism symptoms in 2-year-olds indicates that social deficits may include

limited eye contact and gestures, preference for being alone, infrequent shared affect or joint attention, and lack of interest in social games and turn-taking. In addition to delays in the development of expressive language, children may also display limited vocal and motor imitation, lack of pretend play, abnormal quality of vocalizations, and poor responsivity to speech. Some children may display stereotyped motor mannerisms or preoccupation with parts of objects in the second year of life; however, expression of repetitive behaviors can be relatively mild in some young children before 3 years of age and can become more pronounced in the preschool years. This pattern has led some experts to caution that ASD cannot be ruled out in very young children who appear to present with autistic impairments in social communication but do not meet full diagnostic criteria because repetitive behaviors are not prominent (Lord 1995; Lord et al. 2006). Regression is reported in 20–30% of cases, though there is variability in the definition and manifestation of regression, with some children showing atypical development prior to regression, some children showing developmental slowing or plateau, and others showing clear loss of skills previously acquired.

In the second year of life, prior to the second birthday, deficits in eye contact, pointing, and general social engagement are also indicative of later autism. One study identified early markers of autism in infants at 12, 18, and 24 months of age (Barbaro and Dissanayake 2012). At all three time points, poor eye contact and lack of pointing were correlated with higher rates of autism as the children aged. Between 12 and 18 months of age, deficits may be observed in gaze shifting, shared affect, joint attention, gesture use, rate of communication, language comprehension, and symbolic play (Woods and Wetherby 2003). Additionally, irregular or delayed motor behavior, emotional dysregulation, and reduced levels of activity may also predict later autism diagnoses in young infants. Guinchat et al. (2012) polled parents of children diagnosed with autism and determined that motor problems and passivity were identified by parents in children around 14.6 months of age, who were later diagnosed with autism. Later signs

(e.g., problems with sleep, emotional regulation, and hyperactivity) were noticed by parents when their children were closer to 15 or 16 months old. Even later, parents identified problems with communication and social interactions in their children aged 22.3 months, on average (Guinchat et al. 2012). It has also been documented that infant siblings later diagnosed with ASD showed higher levels of repetitive behavior between 12 and 24 months than high-risk siblings who did not later meet ASD criteria (Wolff et al. 2014).

Prospective studies of infant siblings of children with ASD are now providing documentation of impairments emerging even by the first birthday, including impairments in eye contact, response to name, referential communication, social smiling, and engagement, as well as abnormalities in visual attention, object exploration, imitation and sensory behaviors, and emotional expression (Cassel et al. 2007; Gamliel et al. 2007; Landa and Garrett-Mayer 2006; Ozonoff et al. 2008; Paul et al. 2010; Yirmiya et al. 2006; Zwaigenbaum et al. 2005). It has been found that infants with high familial risk of autism may gesture, request, and initiate joint attention at lower rates than infant not at risk (Rozga et al. 2011). A review of the pertinent literature conducted by Jones et al. (2014) summarized that reduced social smiling, directed vocalizations, and social responsiveness are all predictors of later diagnoses of autism in at-risk infants (Jones et al. 2014).

In contrast to this clear evidence of behavioral symptoms which at 12 months seem to differentiate children who will develop ASD, there is limited evidence of observable behavioral differences at 6 months of age which predict later ASD diagnosis. Research has noted that infant siblings of children with ASD at 6 months of age, even those who will go on to develop ASD themselves, appear to smile and vocalize at others and show clear social interest and engagement (Jones et al. 2014; Rogers 2009; Rozga et al. 2011; Young et al. 2009). In a prospective longitudinal study, researchers found that frequencies of gazing at faces, social smiling, and directed vocalizations were similar between at-risk and matched low-risk infants at 6 months of age, though by 12 months, differences were significant between

groups and predictive of later diagnosis of ASD (Ozonoff et al. 2010). Importantly, the neurodevelopmental processes which will eventually lead to autistic symptomatology may already be in progress at this age; however, existing methods for detecting behavioral symptoms of autism are not sensitive enough to detect disruption at this level. Experimental analyses of basic perceptual and cognitive processes involved in development of social interactions and communication are necessary in order to identify biological or neuropsychological markers indicating risk of autism prior to the emergence of clinical symptoms.

At the conclusion of the first decade of this research enterprise, it is clear that early social communication symptoms of ASD often, though not always, emerge between 6 and 18 months of age and show diverse patterns of symptom onset (Chawarska et al. 2014; Szatmari et al. 2016). Researchers have shown that a diagnosis of ASD made at 18 months of age for an at-risk infant is highly stable through 3 years of age, suggesting that early diagnosis is not only possible but important for early intervention (Ozonoff et al. 2015). However, over half of the infant siblings in this study who eventually received ASD diagnosis at 36 months, had not met diagnostic criteria at 18 months, suggesting that for some children the symptoms continue to emerge over the first 2 years of life. Though at present it is still very difficult to predict the individual trajectories of young children and no single atypical behavior at 12 months of age predicts later ASD diagnosis in all children, these prospective studies are providing evidence that children who will go on to develop ASD can be differentiated from children who will not develop ASD based on aspects of their behavioral presentation at 12 months. For instance, patterns of differences in motor behaviors, imitation, disengaging attention, eye contact, social smiling, social interest, joint attention, response to name, gesture, requesting, and vocalization appear in children who go on to receive confirmatory diagnoses of ASD (Mitchell et al. 2006; Ozonoff et al. 2010; Rozga et al. 2011; Szatmari et al. 2016). These findings indicate both the great strides made in recent years and the need for more specific and accurate

measurements of various behavioral observations in infants, especially those 6 months old and younger.

Future Directions

ASD is currently understood to involve disruptions in early emerging mechanisms of socialization. While the exact etiology is currently unknown, the symptoms which result in a diagnosis of ASD are understood to be the outcome of complex interactions between congenital impairments and the effects of these impairments on subsequent environmental learning opportunities (Dawson 2008). It is assumed that the pathogenetic process which gives rise to objectively observable symptoms of autism in the second year of life is already underway before the full syndrome is expressed and behavioral symptoms are detected. In order to improve early detection, understanding of etiology, and ultimately treatment or prevention efforts, identification of biological markers which indicate risk is critically needed (Klin et al. 2008; Tager-Flusberg 2010). Researchers are conducting detailed experimental analyses of a variety of biological and neuropsychological processes in search of behavioral and neurobiological endophenotypes. It is hoped that prospective collection of a variety of possible measures including biological samples, neuroimaging data, audio and video recordings, as well as data from eye tracking and event-related potential (ERP) methods will soon lead to the identification of measures which reliably predict later ASD classification. For instance, Jones and Klin (2015) used an eye tracking task to show that infants later diagnosed with ASD displayed decreasing fixation to the speaker's eye region between 2 and 6 months of age. Evidence of abnormal brain development has also been observed during the first year of life (e.g., Courchesne et al. 2003), prior to overt behavioral abnormalities. Not only will these results provide greater information about symptom onset and aid in earlier identification of children at risk; they are expected to provide important clues as to the

mechanisms of socialization and patterns of disruption in development which give rise to ASD.

Identification of children who are likely to develop ASD, but before the behavioral symptoms can be detected, provides particularly promising opportunity for intervention to be applied. The majority of evidence-based interventions for autism were developed for preschool and school-age children and have not been validated with infants and toddlers with ASD (Boulware et al. 2006; Koegel et al. 2008; Wetherby and Woods 2006); however, the earlier children are identified as at-risk for ASD, the stronger the ethical imperative to develop interventions applicable to these infants and toddlers. Initiation of intervention in infancy allows for targeting the earliest emerging social communication abnormalities. Intervention at this age, before clinical symptoms have fully emerged, also has the potential to alter these infants' developmental trajectories and reduce the severity of symptom presentation (Dawson 2008).

Research is now emerging supporting the potential positive effects of developmentally sensitive interventions for infants (Rogers et al. 2014). Green et al. (2017) found, in a randomized controlled trial of 7- to 10-month-old high-risk siblings, that a video-based feedback program designed to increase communication between infants and their caregivers resulted in increased infant attentiveness to parents and reduced autism risk behaviors. While additional large and well-controlled trials will be needed to establish treatment efficacy and best practices for infants, pilot studies have been promising and warrant further investigation (Bradshaw et al. 2015).

In conclusion, the past decade has seen tremendous progress in understanding the earliest signs of ASD and illuminating the complexity of identifying infants at risk. The large network of prospective studies of infant siblings of children with ASD has yielded invaluable data and insights. It is anticipated that research efforts over the next several years will continue to refine early markers of risk for ASD and provide more clear guidance regarding effective treatment and even prevention approaches.

Infant-Toddler Social and Emotional Assessment (ITSEA)

Alice S. Carter

Department of Psychology, University of Massachusetts Boston, Boston, MA, USA

Description

The Infant-Toddler Social and Emotional Assessment (ITSEA) is an empirically validated clinical tool that was developed to assess social-emotional and behavior problems as well as delays or deficits in the acquisition of competencies that may arise between the ages of 12 and 36 months. The ITSEA includes parent and childcare provider forms that can be completed independently as a questionnaire or administered verbatim as an interview. The ITSEA was designed to provide a comprehensive profile of social-emotional and behavior problems and competencies and includes the following domains and subscales: (1) Externalizing, which is comprised of the Activity/Impulsivity, Aggression/Defiance, and Peer Aggression subscales; (2) Internalizing, which is comprised of Depression/Withdrawal, General Anxiety, Separation Distress, and Inhibition to Novelty; (3) Dysregulation, which is comprised of Negative Emotionality, Sleep Problems, Eating Problems, and Sensory Sensitivity; and (4) Competence, which is comprised of Attention, Mastery, Motivation, Imitation/Play, Empathy, and Prosocial Peer Relations. There are also three Item Clusters, Maladaptive, Social Relatedness, and Atypical, which include clinically significant behaviors that occur rarely in the general population as well as an additional ten infrequently occurring items of clinical significance that did not fit neatly in any of the domains, subscales, or item clusters (e.g., runs away in public places). The ITSEA also includes questions about parental concern.

The ITSEA items are rated on a three point scale (0 = “Rarely/Not True of My Child”; 1 = “Sometimes/Somewhat True of My Child”; 2 = “Often/Very True of My Child”). The Parent Form

is written at a fourth- to sixth-grade level and takes about 25 min to complete. An important feature of the ITSEA for use with young children with or at risk for autism spectrum disorders (ASD) is that all of the scales can be scored for nonverbal children. For some items, a “No Opportunity” response is offered, for example, if parents have not had the opportunity to observe their child engaging in particular behaviors with peers.

The ITSEA can be scored by hand or with a computer scoring program. Cut scores at the 10th percentile, reflecting the *Of Concern* range, are offered for domains, subscales, and item clusters. In addition, T scores, with a mean of 50 and a standard deviation of 10, are provided for domain scores. In addition to reviewing the specific pattern of scores that are in the *Of Concern* range, tables are provided that show how unusual it is for children to obtain multiple *Of Concern* scores within and across domains. For example, in the normative sample, 21.3% of girls had at least one Internalizing subscale in the *Of Concern* range, but only 5.3% of girls had more than one Internalizing subscale in the *Of Concern* range (Carter and Briggs-Gowan 2006).

The ITSEA is published and distributed by Pearson Assessment in English and Spanish. It has been translated and used in research in many other languages, including Dutch, French, Turkish, Hebrew, Portuguese, Mandarin, Cantonese, German, and Arabic.

Data on ITSEA profiles for children with autistic disorder is presented in the ITSEA manual (Carter and Briggs-Gowan 2005). A comparison of children in the national standardization sample to children with autism referred from early intervention clinics whose diagnoses were confirmed by clinical impression and with both the Autism Diagnostic Observational Scales (ADOS; Lord et al. 2000) and the Autism Diagnostic Interview Revised (Rutter et al. 2003) revealed the following:

Consistent with expectations, there were striking differences between children with autism and age-matched controls in the normative sample in the Competence domain and subscale scores with very large effect sizes. Striking differences (with

large effect sizes) were also observed in the Maladaptive, Social Relatedness, and Atypical Index Clusters. Differences were also observed in the Dysregulation domain, with children having autism rated as having more problems in the Eating, Negative Emotionality, and Sensory Sensitivity subscales. Statistically and clinically significant differences were also seen in the Internalizing domain Depression/Withdrawal subscale and the Externalizing domain Activity/Impulsivity subscale, with children with autism rated as having more problems in these areas. Children with autism were rated as having fewer problems on the Peer Aggression subscale, possibly reflecting their lack of engagement with or interest in peers.

The BITSEA (Briggs-Gowan and Carter 2006; Briggs-Gowan et al. 2004) is a briefer screening tool that can be used in pediatric, early intervention and childcare settings. It is comprised of 42 ITSEA items, with 11 items contributing the Competence Scale and 31 items contributing to the Problem Scale. The BITSEA is designed as a broad social-emotional and behavioral health screener, but appears to be sensitive and specific as an ASD screener (Briggs-Gowan and Carter 2006). Although not a focus of this entry, the BITSEA has demonstrated strong psychometric properties and parent acceptability (Briggs-Gowan et al. 2004).

Historical Background

Development of the ITSEA started in the early 1990s, in recognition that there were no questionnaires to assess problem behaviors in the first years of life. The selection of items and development of the ITSEA scales and domains began with a review of the relevant developmental psychology and psychopathology literatures, with a focus on early emerging, clinically significant behaviors that can be reliably assessed in 1- and 2-year-old children. In addition to clinical case studies and research articles, several diagnostic manuals were reviewed, including the Diagnostic and Statistical Manual – Fourth Edition, Text Revision (DSM-IV-TR; American Psychiatric Association

[APA] 2000), and the Diagnostic classification of mental health and developmental disorders of infancy and early childhood (DC: 0–3; Zero-to-Three 1994) to ensure comprehensive coverage of symptoms relevant to early emerging psychiatric conditions. Based on this review, three Problem domains were included: Externalizing, Internalizing, and Dysregulation. For comprehensive coverage, symptoms of rare disorders (e.g., Tourette Disorder, Post-Traumatic Stress Disorder) were also included.

Including the Externalizing and Internalizing domains was consistent with (Achenbach's 1966) extensive work in defining these broad domains and a then emerging consensus that these problems could be identified in early childhood. The inclusion of scales to address problems with the regulation of mood, state (sleep and eating), and sensory sensitivities was deemed particularly relevant for infants and toddlers. The Competence domain was included in an effort to comprehensively characterize early social-emotional adjustment and because the presence of social-emotional competence was viewed as minimizing the emergence and persistence of problem behaviors. In addition, by asking caregivers to rate both problems and competencies, response biases may be minimized.

As part of the development of the ITSEA, each of the items included in the ITSEA were reviewed by a panel of experts who rated developmental appropriateness as well as content fit on subscales and domains. Focus groups were conducted with parents and childcare providers to evaluate comprehensiveness and ease of item comprehension. In addition, items were evaluated in an epidemiological sample and in a national standardization sample for psychometric properties. Acceptability for the ITSEA was very strong, with over 90% of parents indicating that they would recommend the ITSEA to a friend with a young child.

The ITSEA was first piloted in a pediatric setting and then included to assess infant-toddler mental health in a large epidemiological sample. Most recently, it has been nationally standardized for 1- and 2-year olds. An upward extension to age 6 years is planned.

Psychometric Data

The version of the ITSEA Parent Form that is currently published by Pearson Assessment was standardized and normed based on a nationally representative sample that was stratified to match the 2002 US Census. Unfortunately, at present, although the ITSEA Childcare Provider Form item responses and scales can be compared to the Parent Form, there are no Childcare Provider Form norms. The ITSEA Parent Form domains and subscales have adequate-to-good internal consistency, good-to-excellent test-retest reliability, and strong inter-rater reliabilities in the national normative sample, which is consistent with earlier work in an epidemiological study (Carter and Briggs-Gowan 2005). Specifically, in the normative sample, the internal consistency or reliability of the ITSEA Parent Form domains ranged from .85 to .89 for girls and from .85 to .89 for boys. Test-retest coefficients ranged from .76 for Competence to .91 for Dysregulation. Inter-rater reliabilities across parents ranged from .72 for Internalizing to .79 for Competence. The ITSEA also has demonstrated strong validity based on confirmatory factor analytic work (Carter et al. 2003), and strong validity in relation to other measures such as the CBCL 1.5–5 (Achenbach and Rescorla 2000), the Ages and Stages Social-Emotional Questionnaires (ASQ: SE; Squires et al. 2002), the Adaptive Behavior Assessment System: Second Edition (ABAS-II; Harrison and Oakland 2003), and scores on the Bayley Scales of Infant and Toddler Development – Third Edition (Bayley III; Bayley 2006).

Clinical Uses

The ITSEA is an appropriate tool for evaluating a 1- or 2-year-old when the goal of an assessment is to gather a comprehensive profile of a young child's social-emotional and behavior problems and competencies. Thus, the ITSEA may be most appropriately used in the early stages of a clinical evaluation to get an idea of the parents' perceptions of the child's current social-emotional functioning. Although not a diagnostic tool, items

in the ITSEA can inform further inquiry about multiple aspects of social-emotional and behavioral functioning as well as symptoms relevant to ASD and other diagnostic statuses. Thus, while ITSEA items do not address symptom onset, offset or duration, which are required for assigning diagnoses, responses to ITSEA items do provide clinicians with initial information about whether or not in the past month a symptom was present, and if present, the frequency or extent to which the behavior was present. The ITSEA also provides information about the absence of social-emotional competencies, which, for very young children, may be critical for raising concerns about a diagnosis of ASD. Problems are assessed with the Externalizing domain, including symptoms of disruptive behaviors, the Internalizing domain, including symptoms of anxiety, depression, and temperamental shyness or inhibition, and the Dysregulation domain, addressing emotional reactivity and regulation, sensory processing difficulties, and sleep and eating problems. It is not unusual for parents to report clinically concerning behaviors on the ITSEA that are reflected in clinically elevated scores on multiple domains and subscales, yet not be concerned about their young child's behavior or social-emotional development. This may be due to parents' limited knowledge of typical development in this age range. It can be extremely useful for the clinician to have knowledge both about the behaviors that the parent is observing and their level of concern about these behaviors prior to beginning a clinical feedback session.

If using the ITSEA as part of determining eligibility or need for services, it is recommended that the ITSEA be coupled with direct observation of the child and discussion with the parents to better contextualize the caregivers' responses on the ITSEA. Research on young children with ASD has used the ITSEA to document relations between sensory sensitivities and anxiety symptoms (Ben-Sasson et al. 2008; Green et al. 2012). The ITSEA may be useful in documenting the presence of unusual behaviors such as social withdrawal and limited or atypical eye contact,

repetitive behaviors and sensory sensitivities. In addition, it is particularly effective in documenting severity of delays or deficits in competencies such as imitation and play, prosocial peer relations, empathy, attention, and compliance. Moreover, as many children with autism also evidence problems in eating and sleeping, elevated anxiety, and attentional problems that are not central to their ASD symptomatology but that may be crucial for appropriate intervention planning, gathering information about both autism-specific symptoms as well as broader information about social-emotional adaptation is warranted. The ITSEA provides a relatively quick and efficient method for obtaining a great deal of information about caregiver appraisals regarding a comprehensive set of social-emotional problems and competencies that can inform both autism spectrum disorder diagnosis and the need to assess further to identify co-occurring emotional and behavioral concerns.

Inferior Colliculi

Sara Jane Webb

Psychiatry and Behavioral Sciences and UW Autism, Seattle Children's Research Institute, University of Washington, Seattle, WA, USA

Definition

The inferior colliculus is part of the central auditory system; specifically, it is located in the tectal region of the midbrain, posterior to the superior colliculus, and anterior to the trochlear nerve. The inferior colliculus is the “site of brain stem convergence and multisensory integration” (Winer and Schreiner 2005, p. 3) containing neurons that are sensitive to interaural timing and intensity difference, which are important in sound localization. Other functions that have been shown to be related to this structure include sound integration, multisensory integration including startle reflex and vestibuloocular reflex, and amplitude modulation of frequencies necessary for detection of pitch.

As part of the central auditory pathway, the inferior colliculus receives projections from the superior olivary nuclei and the cochlear nuclei via the lateral lemniscus. The inferior colliculus sends projections to the medial geniculate nucleus, which in turn projects to the primary auditory cortex. The inferior colliculus consists of three regions – central nucleus, lateral nucleus, and dorsal cortex. The central nucleus is exclusively involved in auditory processing and is necessary for normal hearing. The central nucleus has numerous layers, arranged in a tonotopic map that is orthogonal to the layers. The lateral nucleus is multisensory, receiving both auditory and nonauditory input. The dorsal cortex receives projections from the cerebral cortex including auditory and somatosensory information. For an in-depth perspective of the inferior colliculus, please see Wilner and Schreiner *The Inferior Colliculus* (2005).

In animal models of autism, the gene *autism susceptibility candidate 2* (Auts2) is expressed in

the inferior and superior colliculi at embryonic day 19 of the mouse brain (Bedogni et al. 2010). Immunoreactive staining in the murine brain found high density of serotonin (5-HT) fibers in the inferior colliculus (Williams et al. 2005); selective serotonin reuptake inhibitor therapeutics are often prescribed in autism. In general, preclinical and animal models have implicated the brainstem in ASD (e.g., Hashimoto et al. 1995; Rodier 2002), but the specificity to the inferior colliculus is unclear.

Functional activity of the inferior colliculus can be assessed via wave V of the brainstem evoked auditory potential (BAEP), which is thought to result from activity of the upper pons and inferior colliculus. Rosenhall et al. (2003) found increased BAEP wave III-V interpeak intervals in children with autism; Chen et al. (2003) found children with autism had longer latencies in wave III and V, as well as increased wave I–II and I–V interpeak latencies. However, a number of other reports (as reviewed in Minshew et al. 2006) have not found consistent abnormalities in BAEP in individuals with autism or their family members. Deficits in tone perception in ASD have been found even in those children with intact click BAEPs; the authors suggested that early abnormal auditory pruning in the lateral lemniscus and inferior colliculus may lead to disrupted connections between the brainstem and cortex and impact auditory processing of linguistic cues (Russo et al. 2008).

Inferior Parietal Area

Jonathan Kopel
Texas Tech University Health Sciences Center
(TTUHSC), Lubbock, TX, USA

Synonyms

Inferior parietal gyrus

Definition

Autism spectrum disorder (ASD) is characterized by altered connectivity in cortical regions,

such as the inferior parietal lobe, involved with communication and emotion regulation (Hanaie et al. 2016). The inferior parietal lobe integrates sensory and motor information to generate spatiotemporal representations (Hanaie et al. 2016). Among ASD patients, several studies have shown reduced gray matter and cortex in the inferior parietal lobe (Brieber et al. 2007; Wallace et al. 2010). Furthermore, these studies suggest that cortical thinning of the parietal and temporal cortices results from abnormal cortical growth in ASD patients (Wallace et al. 2010). Further research is required to elucidate the atypical neural growth and developmental mechanisms observed in ASD patients.

[Inferior temporal gyrus](#)

Definition

The inferior temporal gyrus is positioned within the temporal lobe below the middle temporal sulcus. It runs the course of the temporal lobe from the anterior temporal pole back to the inferior occipital gyrus. It extends down to the ventral or bottom surface of the brain where it stops at the inferior sulcus. Functionally, this area of the cerebral cortex is associated with higher-level visual processing. That is, it helps us to determine what we are seeing and contains regions sensitive to complex object features as well as particularly important categories of objects, such as faces and letters.

Informal Assessment

Cory Shulman
The Paul Baerwald School of Social Work, The
Hebrew University of Jerusalem, Jerusalem,
Israel

Definition

Informal assessment of individuals with autism spectrum disorders (ASD) involves the collection of information about the individual, interpreting that information and applying it in a systematic manner, the purpose of which is to better understand the individual's abilities. Although the overall goals of informal and formal assessment are similar, they differ in the use of the information collected, the manner in which the information is collected, and the type of information collected. The specific purpose of informal assessment is usually to use the information collected in order to set goals, identify intervention strategies, and measure intervention outcomes. In formal assessments, information is collected through the use of standardized, norm-referenced tests, whereas in informal assessment, information is based on careful observation of behaviors by the examiner. Types of information accumulated during the process of informal assessment include profiles of behavior, of capabilities, of learning style, and of motivational strategies, which then serve to assist in the selection of techniques to facilitate development, to set learning goals, and, in general, to support the individual's progress.

Historical Background

Historically, assessment procedures focused on the formal collection of information in areas of

concern for individuals with special needs or for those involved in the care of these individuals. Specifically, data were collected in order to substantiate strengths and weaknesses of the individual. The information was traditionally based on results from standardized testing of intelligence, aptitude, and academic abilities, as well as a medical history and current physical status as part of the assessment battery. The assumption was that the comparison between individuals would be more informative if each person was assessed in a similar manner. Over time, it became clear that, although this type of assessment provided some important information about individuals with ASD, the results obtained needed to be interpreted with caution because the results obtained in formal assessments did not necessarily reflect the abilities of the individual with ASD. In addition, these data did not assess the interactional or motivational aspects of the individual but rather focused on whether or not the individual could perform particular skills. Despite the difficulties with systematic assessment of information, informal assessment continued to be perceived as less professional than formal evaluations until the latter part of the twentieth century, when informal assessment procedures were incorporated into the assessment necessary for the development of the individualized education (IEP) objectives mandated by law (PL-94-142).

Current Knowledge

As a result of recent changes in assessment, the reliance on formal tests has given way to a more person-centered approach (Lord et al. 2005). Professionals acknowledge that assessment needs to recognize changes in behavior and not focus exclusively on successful task performance. Informal assessment procedures target not only what individuals know but also how they interact with the environment and how they learn and understand and function in the world around them. Informal assessment techniques do not require comparative norm-referenced groups against which to measure individuals' performance but rather individuals' performance is gauged by

comparison to their own performance levels within the specific demands of the situation or programs. Assessment differs from diagnosis in that while diagnostic evaluation addresses the grouping of common features under the same label, assessment refers to evaluating the unique and distinctive characteristics of the individual (Klin et al. 2005). A diagnosis may assist in establishing eligibility for intervention services, whereas an assessment identifies the unique and specific profile of strengths and weaknesses of a particular individual. Although many people may share the ASD diagnostic label, the manifestation of ASD in each individual is different, necessitating personal assessment. The purpose of such an assessment is to facilitate the development of individualized educational and behavior management programs tailored to the specifications of the individual (Hogan and Marcus 2008). Thus, in contrast to the process of diagnosis, which examines common characteristics in individuals with ASD, assessment looks at the unique aspects of individuals as the basis for the development of appropriate intervention plans.

Both formal and informal diagnostic assessments yield information which aids in the confirmation of diagnosis by detailing the specific syndrome expression in a particular individual, but informal assessment also augments diagnostic ascertainment with information regarding the identification of intervention needs and/or by providing a method to assess the effects of treatment. To highlight the similarities and differences in the information provided by informal and formal assessments, school psychologists were presented with information gleaned from formal or informal assessments and asked diagnostic and prescriptive questions about the children based on the information provided. Some qualitative differences in the efficacy of the information provided by each of the two types of assessment emerged. The behavioral descriptions from informal assessments provided the type of information necessary for identifying autistic symptomatology more correctly than information from formal assessments (Levy et al. 2009). While the information from both formal and informal assessments was found to be helpful in making Individualized

Educational Program (IEP) decisions, the suggested goals which emerged from each type of assessment were in different domains. Data from informal assessments led to goals in the areas of receptive language and behavior, whereas data from formal assessments led to academic goals, such as reading. In conclusion, this research reinforced the need for the information acquired from each type of assessment. Those who had received reports based on formal assessments requested more informal information and those who had received informal assessment information desired more formal data (Spears et al. 2001). Thus, the complementary information which is obtained from formal and informal assessments is essential to a comprehensive understanding of individuals with ASD.

The goals of informal assessment include gaining the most valuable information about individuals for whom traditional testing situations are inappropriate. Significant impairments in language and communication have an impact on the ability of these individuals to comprehend the language demands of standardized testing procedures. In addition, the social deficits in reciprocity and social cognition which are central to ASD present particular challenges when testing individuals with ASD. Finally, the behavioral and cognitive issues revolving around motivation, sensory interests, and repetitive, restricted areas of interest necessitate adaptations which often invalidate the standardized procedures of administration (Volkmar et al. 2005). Thus, because standardized assessments require the understanding of verbal instructions, are based on social reinforcement, and entail compliance, informal assessments are recommended for individuals with ASD (Lerman et al. 2004). Informal assessment is based on direct behavioral observations. This is accomplished through clinical observations of the individual's functioning in natural settings or in a formal assessment context, and data may be collected in a variety of settings, including classroom, workplace, home, clinic, and others. The physical environment, task presentation, level of interest, and past learning experience can all influence the assessment results and must be considered in understanding the results

from the assessment. Informal assessment requires no formal time constraints or standardized procedures, and therefore, the examiner can become more familiar with the individual and establish rapport.

Designing an assessment to elicit certain behaviors can also provide salient information. Therefore, it is important to take the individual behavioral expression of the triad of impairments upon which the diagnosis of ASD is based (American Psychiatric Association [APA] 2000) into consideration during informal assessments. Noting communication strategies, social interactional patterns, and repetitive, restrictive behaviors is an integral part of any assessment for individuals with ASD. For example, careful attention should be paid to the manner in which the individual asks for help. Likewise, it is important to note with whom the individual chooses to spend time and what behaviors affect the interactions. These parameters change according to the age and level of functioning of the individual being assessed. For example, when assessing a young child with ASD, it may be appropriate to allow the child to choose the object, task, or activity, thus beginning with a high interest task in order to maximize motivation. It is within the nature of this type of assessment that the examiner is free to vary the number and order of tasks. Examiners should be sensitive to the child's activity level, attention span, and tolerance for highly structured activity when presenting the different types of tasks. It has been found helpful, especially with developmentally young children, to balance activities between those which are sedentary and require focused attention and those which are more physical in nature in order to maintain interest and avoid frustration. Most evaluations of this type continue approximately 30–40 min, but they can vary in duration. Assessments such as these should be conducted in a relatively quiet, brightly lit room, but, if appropriate, can incorporate any space and activity such as walking in unfamiliar areas, which provides an opportunity to see how the child reacts to new places, people, and even experiences. Throughout the session, the quality and the quantity of the child's spontaneous initiations in language and behavior should be noted.

The behaviors observed during informal assessments should be recorded as they occur (Herzinger and Campbell 2007). While conducting an informal assessment, the examiner should find a way to document behavior as it appears in order to capture the quality of what is happening as well as the behavior itself. In order to facilitate data collection, it is crucial to establish a method which allows the examiner to take notes about each task, as well as to get an overall view of the items presented. In order to make basic decisions regarding educational placement, services required, and initial programming suggestions, it is necessary to interpret the information. The interpretation should include summary points as well as precise and detailed examples of behavior observed, which then serve as the basis for specific intervention recommendations. Informal assessment of individuals with autism spectrum disorders is a challenging task and involves expertise from various disciplines. Multidisciplinary teams work together to decide what information should be collected in order to understand the individual, and once the information has been collected, they are instrumental in interpreting the significance and implications of this information for the individual. In summary, clinical observation of individuals with ASD is a valuable skill. Despite its complexity, it should lead to a more comprehensive understanding of the person and, as a result, a more individually tailored treatment/intervention plan.

Informal assessment is dependent on making the assessment appropriate for the child's developmental level, bearing in mind that individuals with ASD often have uneven profiles of strengths and weaknesses. It is important to remember that no matter how much clinical and diagnostic information has been gained from an initial evaluation, it may or may not be representative of the individual's functioning in other settings or with other people. In order to put initial evaluation information into perspective, it is helpful to solicit certain information from other sources such as parents and professionals. A parent interview can often provide supplementary information which assists in the interpretation of the information gleaned from informal assessment.

If possible, parents should be interviewed while their child is not present. Parents and other professionals can add specific information about the child's cognitive and language abilities, as well as behavioral issues which may help the examiner make decisions regarding the results of the initial evaluation.

Since successful informal assessment is based on the clinical observational skills of the examiner rather than the specific tasks presented, the tasks themselves become less important. The value of the tasks in informal assessment lies in the fact that they serve as a vehicle for the examiner's observations, with more emphasis placed on other elements which can supply important information regarding the individual being assessed. For example, using appealing and developmentally appropriate materials is central to informal assessment. But carefully choosing the materials used in an assessment, it becomes possible to assess the individual's potential for creativity and interaction, to elicit cognitive and behavior styles, and to assess the conditions under which the individual is more likely to communicate and be socially involved. Thus, the observational skills of the examiner are far more important than the specific tasks which provide the context for the observed behavior. The examiner must be able to remain flexible and react individually according to the individual's interactive style and needs (National Research Council [NRC] 2001). Considerable clinical skill and experience are therefore needed in the use of informal assessment procedures. Above and beyond the results from standardized testing, informal assessment is an attempt to capture abilities and disabilities and behavior as they affect the individual's daily life (Klin et al. 2005).

Few guidelines exist for conducting informal skill assessments or for interpreting the results with individuals with ASD. Some suggestions include evaluating the child's performance on tasks from preexisting curriculum (Callahan et al. 2011), while others propose assessment of reinforcement techniques (Lerman et al. 2004). Herzinger and Campbell (2007) recommend using informal functional assessment techniques which focus on the child's everyday adaptive

functioning. Assessing behavior is an ongoing process designed to guide treatment planning. The results, describing characteristics and identifying the unique functional profile of each individual, can be used in planning intervention services. Informal assessment involves careful observation and integration of available information, while checking to see if additional information is necessary in order to develop a treatment plan. After delineating the various components of a possible intervention, treatment priorities need to be set by the parents and/or the professionals concerned. A treatment plan must be implemented after careful analysis of the information collected through informal assessment procedures outlined above. A mechanism for tracking individual progress and a system for ongoing assessment permit timely adjustments to the intervention program. Thus, informal assessment documents functioning before, during, and after intervention and is crucial for evaluating changes and progress over time. Employing assessment information in order to measure post intervention status is one way to evaluate treatment decisions and to specify the aspects of intervention which succeeded with a particular individual. In sum, ongoing informal assessment should be a part of every intervention program in order to monitor the child's progress toward established goals and aid in decision making in future interventions (Magiati and Howlin 2001). The assessment of individuals with autism spectrum disorders is a challenging task and involves expertise from various disciplines. The triad of impairments present in ASD makes formal assessment of individuals with ASD problematic and the incorporation of informal assessment techniques critical.

Future Directions

In order to be effective, the scope of informal assessment must be as broad as the number of individuals being assessed. The tension between deciding on the elements to be observed and evaluated in informal assessments and the flexibility necessary for adapting the assessment to each individual with ASD seems

insurmountable. The challenge inherent in informal assessment of individuals with ASD lies in abstracting the elements in present behavior from which future behavior can be inferred (NRC 2001). Assessment is an attempt to examine and understand human nature and as such is imperfect. Goals for improving informal assessment include training qualified personnel who are familiar with the characteristics, response patterns, and behaviors which are typical of individuals with ASD. In addition to understanding ASD, training should include a basic understanding of informal assessment, and best practices in ASD, including monitoring outcomes. Many types of informal assessment procedures exist, and the professional must select the measures most appropriate for the individual with ASD being assessed. Informal assessment involves daily and ongoing evaluation of skills and behavior in order to monitor treatment outcomes (Hogan and Marcus 2008). It is particularly important to incorporate interactive modifications in the environment. It is also important to work collaboratively in order to create optimal intervention programs for individuals with ASD.

Information Processing Speed

Emily S. Kushner¹ and Gregory L. Wallace²

¹Center for Autism Spectrum Disorders, Division of Neuropsychology, Children's National Medical Center, Washington, DC, USA

²Psychiatry and Behavioral Sciences and Pediatrics, School of Medicine and Health Sciences, The George Washington University, Washington, DC, USA

Synonyms

Inspection time; Reaction time

Definition

Information processing speed represents an underlying efficiency of perception, reasoning, and problem solving. This efficiency can dampen or enhance an individual's innate intellectual capacities. Processing speed tasks are often included in tests of intelligence and comprise their own index (e.g., Processing Speed Index in the Wechsler scales), although impaired motor skills can impact cognitive processing in these tasks. However, independent inspection time (IT) tasks are generally considered the purest assessments of information processing speed. IT is the amount of time a person needs to be exposed to a stimulus in order to make a simple perceptual judgment (e.g., which line is longer?).

Recent research using the IT task, which is free of motor demands, reveals superior processing speed among lower functioning children with autism spectrum disorder (ASD) and intact (but not superior) processing speed among higher functioning children with ASD. Across development in typically developing individuals, IT performance is consistently correlated with general intelligence. However, IT does not appear to have the same relationship with intelligence in ASD that is seen in individuals with typical development.

Initial Communication Processes Scale

Trina D. Spencer

Rightpath Research and Innovation Center,
University of South Florida, Tampa, FL, USA
Institute for Human Development, Northern
Arizona University, Flagstaff, AZ, USA

Definition

The Initial Communication Processes Scale is an observational assessment instrument that assesses preverbal and verbal communication of young children (0–36 months). Domains addressed by the Initial Communication Processes Scale include auditory, visual, manual fine motor, oral vocal motor, object play manipulation, object play symbolic, problem solving, affective development, communication skills, and comprehension skills. It can be used to help identify the presence of autism-related communication deficits in children under 3 years old. Although developed in the early 1980s, applications of the Initial Communication Processes Scale have appeared rarely in the literature.

Definition

Initiating behavioral requests (IBR) refers to a child's use of eye contact, reaching, giving, or pointing to coordinate with another person to request help in obtaining an object or event. IBR is contrasted with responding to behavioral requests (RBR), which is a child's skill in responding to gestural or verbal directions to obtain an object or event. Along with joint attention behaviors and social interaction behaviors, behavioral requests (initiating and responding) are included in the Early Social Communication Scales (ESCS). The ESCS measures nonverbal communication skills of children between 8 and 30 months of age and is used in research and practice. Many young children with autism display deficits in initiating joint attention (IJA) but

Initiating/Responding to Joint Attention Skills (IJA/RJA), Table 1 Behavior regulation and joint attention gestures^a

General category	Specific skill	Definition	Example
Behavior regulation	Pointing	Child points to an object, person, or event that he or she wants or needs	Child points at a toy on the shelf to indicate that he or she wants to play with it
	Giving	Child gives an object to request help	Child gives a sealed bag of candy to his or her mom to communicate that he or she wants it open
Initiating joint attention	Pointing	Child points at an object or event to share his or her interest	Child points at a dog to share his or her interest about the dog
	Alternating eye contact	Child alternates eye gaze between an object or event and a person to share his or her interest	Child looks back and forth between a dog and his or her mom to share interest about the dog
	Showing	Child holds up an object to share his or her interest	Child holds up a drawing to share with his or her teacher
Responding to joint attention	Pointing	An adult points to something to share his or her interest. The child looks in the direction of the point	An adult points to a neat poster on the wall, and the child looks at the poster

^aThese skills were selected based upon Early Social Communication Scales Manual (Mundy et al. 2003)

Definition

As explained in the section titled “joint attention,” children with autism exhibit a core deficit in joint attention. Joint attention initiation refers to communication used to share interest regarding an object, person, or event with someone else (Mundy et al. 1986). Most commonly, joint attention is initiated by young children through the nonverbal gestures of pointing, showing, giving, and coordinated looking. Responding to joint attention requires that a social partner visibly acknowledges the joint attention initiation of their communication partner. Table 1 provides definitions of specific types of initiating and responding joint attention gestures as well as a few examples of these gestures.

Mundy, P., Sigman, M., Ungerer, J., & Sherman, T. (1986). Defining the social deficits of autism: The contribution of non-verbal communication measures. *Journal of Child Psychiatry*, 27, 657–669.

Definition

The initiation of communication refers to the nonprompted and purposeful (i.e., intentional) sending of a message from one conversational partner to another within the context of a communicative exchange. The form of the message may be nonverbal (consisting of some combination of eye gaze, gestures, and/or vocalizations)

or verbal (consisting of single words or word combinations). In general, the individual who initiates the communication act would be considered the speaker and the individual to whom the communication act is directed would be considered the listener. The initiation of communication can serve the pragmatic function of requesting when the speaker is attempting to elicit assistance in obtaining some instrumental goal. Alternatively, the initiation of communication can serve the pragmatic function of joint attention when the speaker is attempting to direct the attention of the listener to an object, action, or event of shared interest. In contrast to a prompted response, initiations require individuals to independently formulate and produce their own communicative behavior without the assistance or contextual support of a communication partner.

Injuries in Children with ASD

Carolyn DiGuseppi

Department of Epidemiology, Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO, USA

Synonyms

[Trauma](#); [Wounds](#)

Definition

Injury may be defined as physical damage to the body caused by sudden or brief exposure to energy at levels that exceed what the body can tolerate (Peden et al. 2008). The energy that most commonly causes injury is mechanical, for example, impact with a moving or stationary object as in a road traffic crash. Other types of energy that cause injury include thermal (e.g., from a flame or hot water), chemical (e.g., from a poison), and electrical energy. Most injuries to children are unintentional, that is, not deliberately caused, for instance, falls, burns, and drowning. Intentional injuries resulting from acts of violence to oneself or by another person, such as assault or suicide, also occur in children, especially during adolescence (Pinheiro 2006). Injuries are a major cause of emergency treatment, hospitalization, death, and disability in children worldwide (Global Burden of Disease Pediatrics Collaboration 2016). Annually, tens of millions of children are injured seriously enough to require medical attention, and more than half a million children die of their injuries.

Compared to adults, children are at greater risk for some types of injuries because their physical and cognitive abilities are still developing and they may fail to perceive or respond to danger (Schwebel and Gaines 2007). The risk of injury is strongly influenced by characteristics of the child, including age, sex, disability, and psychological and behavioral characteristics such as activity level and cognitive function (Schwebel

Initiation of Joint Attention

► [Initiation of Communication](#)

and Gaines 2007). The environment in which the child lives also influences injury risk. This includes both the physical environment, whether natural or man-made, i.e., home, school, roads, and surrounding community, and the social environment, e.g., maternal education, caregiver supervision practices, family relationships, household income, neighborhood cohesion, peer and cultural norms, economic and health policies, and laws.

Several risk factors for injury occur at higher rates in children with autism spectrum disorder (ASD) compared to the general population, including male sex and psychological and behavioral problems such as aggressive behavior, anxiety, attention deficits, cognitive delays, hyperactivity, and sensory deficits (Lyall et al. 2017). While these characteristics could place children with ASD at higher risk for injury, research studies examining injury risk have reported conflicting findings ranging from significantly increased risk to little or no increased risk associated with ASD. The differing results likely reflect methodological variation between studies, including the populations sampled, the definitions used for injury, the data collected, the periods of risk, and the specific sociodemographic, clinical, and behavioral characteristics included as covariates in analytic models. Whether children with ASD are more likely than are other children to suffer injury has not been definitively established.

A wide range of effective strategies exists to prevent, control, and ameliorate the consequences of child injuries (Peden et al. 2008; Pinheiro 2006; Schwebel and Gaines 2007). Legislation and enforcement, such as setting and enforcing laws mandating passenger restraint use, have been shown to prevent child injuries. Product and environmental modification is another key prevention strategy, for example, isolation fencing for swimming pools and child-resistant packaging of medications and poisons. Safety devices, including car safety seats, smoke detectors, bicycle helmets, and window guards, are effective when used correctly in reducing injury occurrence or severity. High-quality supportive home visits have short- and long-term

preventive effects on injury and violence to children, including reductions in verified incidents of child abuse, use of physical punishment, family violence, and physician visits for unintentional injuries and poisonings. Reducing access to lethal means, such as guns, poisons, and certain medications, can decrease suicide risk among older children and adolescents. Timely and effective emergency care (e.g., caregiver training in cardiopulmonary resuscitation and prompt response times for emergency medical services), trauma care, and rehabilitation services can lessen adverse outcomes of injuries, such as disability or death.

Inositol: Definition

Jonathan Kopel
Texas Tech University Health Sciences Center
(TTUHSC), Lubbock, TX, USA

Synonyms

Cyclohexitol; Myo-inositol; Vitamin B8

Definition

Inositol is an abundant sugar responsible for important cellular transduction pathways involving hormones, neurotransmitters, and growth factors (Parthasarathy et al.). Among the nine inositol isomers, the myo-inositol has the greatest biological activity and serves to synthesize cell membrane inositol phospholipids (Parthasarathy et al.). In the brain, myo-inositol links several extracellular signaling pathways activating phospholipase C and increasing cytosolic calcium from the endoplasmic reticulum (Parthasarathy et al.). The resulting calcium surge activates many enzymes and receptors controlling essential physiological and neurological functions (Parthasarathy et al.).

As a result, the inositol pathway remains an attractive pharmacological target towards the treatment and management of many psychiatric disorders. Several clinical studies have demonstrated a correlation between decreased myo-inositol levels and the severity of several

psychiatric conditions, including depression, obsessive-compulsive disorder (OCD), and bipolar disorder (Einat and Belmaker 2001; Levine 1997; Parthasarathy et al.). Furthermore, studies supplementing myo-inositol for depression, panic disorders, and OCD patients showed improved symptom severity and management (Levine 1997). Additional pharmacological advancements using inositol synthase inhibitors, valproate and lithium, showed decreased mood fluctuations among bipolar patients (Levine 1997; Parthasarathy et al.). However, similar outcomes among autistic spectrum disorder (ASD) patients remain elusive.

A double-blind trial of myo-inositol showed no significant improvement in nine children with ASD (Levine et al. 1997). Previous scientific studies reported serotonin binding to 5-HT₂, and 5-HT_{1c} receptors activates inositol signaling, which the authors hypothesized should mimic the clinical improvements seen with SSRIs and ASD patients (Levine 1997; Parthasarathy et al.). Despite the similarities, no additional studies have investigated the therapeutic potential of myo-inositol among ASD patients. However, a proton magnetic resonance spectroscopy (H¹ MRS) analysis found myo-inositol and choline were significantly increased in the anterior cingulate and left striatum of autistic children (Vasconcelos et al. 2008). As such, myo-inositol may provide additional diagnostic and radiologic markers for ASD and other psychiatric conditions. In addition, a genome-wide linkage analysis revealed the Inositol-3-phosphate synthase 1 (ISYNA1) gene may act as a potential autism susceptibility locus (Parthasarathy et al.). Current literature shows Inositol-3-phosphate synthase 1 modulates inositol signaling, which may alter neurological symptoms among ASD patients (Parthasarathy et al.). Therefore, further investigation is warranted to elucidate the full therapeutic and diagnostic potential of inositol among ASD patients.

Integrated Play Groups (IPG) Model

Evelynne Green

The University of Vermont, Burlington, VT, USA

Definition

The integrated play groups (IPG) model is an intervention designed to facilitate the development of meaningful peer relationships and appropriate play and social-communication skills in children with autism spectrum disorders (ASD) through adult-supported peer interactions. Play groups consist of “novice players” (those with ASD) and “expert players” (typically developing peers). A trained adult facilitator acts as a “play guide” to support and shape interactions between the novice and expert players.

Historical Background

The IPG model was developed by Dr. Pamela J. Wolfberg in an effort to create a model of intervention “that would bring together children with differing abilities, cultural identities, and social backgrounds for the purpose of play” (Wolfberg 1999, p. 6). Wolfberg received a small grant from a community educational foundation to fund an initial pilot study of the IPG program, and this research later became the subject of her master’s research (Wolfberg 1988). Then, along with Dr. Adriana Schuler, Wolfberg (1992)

codirected a research and demonstration project to further develop and field-test the intervention model. Since then, several small-scale efficacy studies have been conducted with positive outcomes (e.g., Lantz et al. 2004; Yang et al. 2003; Zercher et al. 2001), and in 2008 Autism Speaks awarded Wolfberg a \$444,420 grant to conduct a large-scale study of the IPG model. The traditional IPG model has recently been extended to incorporate sensory integration therapy for children who have been identified as having both social-communication and sensory integration deficits (Fuge and Berry 2004), and has paired with the Friend 2 Friend model to provide collaborative services. A final extension of the traditional IPG model is the Integrated Drama Groups (IDG) model. This intervention was developed to support the social communication of adolescents with ASD using a developmentally appropriate model, which includes opportunities for turn taking and role playing within the context of sociodramatic play (www.autismsocialconnection.org). In 2009, Julius, Schuler, and Wolfberg received the Alexander von Humboldt Foundation Transcoop Research Award with matching funds from the Flora Foundation and the Mendelson Family Foundation to evaluate the efficacy of the IDG model (Wolfberg 2010).

Rationale or Underlying Theory

The IPG model draws heavily from the social constructivist work of Lev Vygotsky, who proposed that it is through play that children acquire “symbolic capacities, interpersonal skills, and social knowledge” (Schuler and Wolfberg 2000, p. 181). Current research indicates that play does indeed serve a fundamental role in social competence, language and literacy development, creative expression, and emotional development in children (for a review, see Wolfberg (1999)). Vygotsky further suggests that a child’s learning and acquisition of skills can be facilitated through scaffolding by an adult or more competent peer within the child’s zone of proximal development, which is the difference between what the child is able to do independently and

what they are able to achieve with assistance (Wolfberg 2003). This provides the theoretical basis for the role of the adult play guide within the IPG model.

Wolfberg (2003) also emphasizes that play is fundamental to a child’s sense of belonging within their peer group, as it is the most valued social activity in childhood. Play contributes to a sense of collective identity and enables children to create a world that is separate and unique from the adult world (Wolfberg and Schuler 1999). Therefore, while play intervention could potentially be provided by an adult therapist alone, typical peers provide the novice player with access to “play culture” in a way that an adult is unable to (Wolfberg and Schuler 1999).

Goals and Objectives

Two of the hallmark characteristics of children with ASD described by *The Diagnostic and Statistical Manual of Mental Disorders-Fourth Edition* (DSM-IV) are a lack of varied, spontaneous make-believe play and a failure to develop appropriate peer relationships (American Psychiatric Association 2000). The primary objective of the IPG model is to facilitate children with ASD in developing mutually enjoyable, appropriate peer relationships, while also increasing their play repertoire to include symbolic play (Wolfberg 1999). Symbolic or pretend play can range from the substitution of one object for another (e.g., pretending a banana is a telephone) to engagement in complex sociodramatic play. Because children with ASD are typically inclined to fixate on certain objects or activities for extended periods of time and limit their involvement with nearby peers, scaffolding and play guidance serve as important supports to guide children through more varied and complex play routines than they would seek out on their own (Wolfberg 2004). Additionally, play materials that have a high potential for sociodramatic and imaginative play are made readily available in the play environment to promote engagement in symbolic play activities (Wolfberg 2003).

Treatment Participants

The IPG model was designed specifically for children with ASD and related disorders ranging from age 3 to 11 years. Wolfberg (2003) suggests that, as play never truly ends, adaptations to the IPG model might be made to support children who are either younger or older than the designated age range. Unfortunately, no efficacy studies have been conducted for ages outside of the recommended age range. It is also recommended that children already have an educational and therapy plan in place before considering participation in an IPG intervention (Wolfberg 2003). This is important because the IPG model was developed as a supplement to more traditional language, social-emotional, and behavioral intervention models.

Participants may be highly verbal to functionally nonverbal and may use augmentative and alternative communication strategies. The IPG model is able to support a wide range of communicative abilities because of its fluid nature. Play groups are designed with the specific child's needs and capabilities in mind. Therefore, a play group designed for a child with strong expressive and receptive language abilities will look very different from one that is designed for a functionally nonverbal child. In addition, play guides and expert players are trained to look at a wide range of behaviors, beyond the obvious gestures of verbal language, as possible attempts at play initiation (Wolfberg 2003). Additionally, visual supports are an integral part of the intervention model, making this model ideal for children already using PECS or for children who simply benefit from visual supports, as many individuals with ASD do.

The IPG model is also designed to support children at all points on the autism spectrum, from those who have intensive forms of autism to those diagnosed with Asperger syndrome. Once again, this is due to the fluid nature of the IPG model, as play activities are tailored to fit the individual child's interests and capabilities. However, it should be noted that the IPG model is not recommended for children whose behavior might be considered self-injurious or pose a threat to

others despite the presence of an adult facilitator (Wolfberg 2003).

Although most children with ASD would likely benefit from the addition of an IPG intervention to their current educational and therapy plan, an ideal candidate would exhibit some impairments in the skills that are necessary for successful play interactions. Some of these deficits might include atypical verbal and nonverbal attempts at social initiation, lack of eye contact, general failure to seek out peer relationships, lack of social or emotional reciprocity, inability to maintain conversation, lack of variation in play, lack of symbolic play, and difficulties taking the perspectives of others (Wolfberg 2003).

Treatment Procedures

The basic setup of the IPG model involves a play group that consists of children with autism (*novice players*), typical peers (*expert players*), and an adult facilitator (*play guide*). The groups are generally made up of 3–5 children, with a higher ratio of expert to novice players. The expert players in the group are recruited from environments in which the novice player would typically come into contact with peers such as school, home, or the surrounding community. It is recommended that the play group meet twice a week for 30–60 min sessions over the course of 6–12 months in an environment where the group members would naturally play, such as a classroom, the home, or community recreation areas (Wolfberg 2003). Play areas are carefully designed to provide a sense of organization and predictability and are stocked with a variety of play materials designed to accommodate the diverse interests and abilities of group members.

Each play session incorporates an opening and closing ritual designed to clearly mark the beginning and end of the session and to foster a sense of group identity. Opening rituals generally consist of a greeting, followed by a review of the play group rules and a brief discussion of the previous play session. These discussions allow children time to consider what was fun or challenging during the previous session to make future

sessions more successful (Wolfberg 2003). The closing ritual includes clean-up of play materials followed by a review of the play session, planning for the next meeting, and a goodbye ceremony that includes a special group song or handshake.

Following the opening ceremony, specific strategies that the children will use during play are reviewed. These strategies are a series of verbal and nonverbal social-communication cues designed to assist both novice and expert players in interacting with one another. For example, a social-communication cue for initiating play might be to stand close, look at your playmates, point to the game, and ask, “what are you doing?” or say, “let’s play” (Wolfberg 2003, p. 190). After this review, the players come up with a simple plan for getting play started. The group might come up with specific themes for play or choose what materials they would like to use. This technique is used only to get play started. As play is naturally fluid, children may change or abandon initial play ideas at any time (Wolfberg 2003).

During the session, the adult play guide facilitates interactions between players by applying four key practices: monitoring play initiations, scaffolding play, providing social-communication guidance, and providing play guidance (Wolfberg 2003). Monitoring play initiations refers to the play guide’s responsibility to recognize, interpret, and respond to a novice player’s attempts to initiate play with peers. If the player’s attempts at initiation are unconventional, the play guide will interpret them for other players and assist the child in learning new, more appropriate means of initiation. Throughout the session, the play guide provides varying amounts of support to players by scaffolding play interactions. This requires that the play guide anticipate times at which players might need support to keep a play interaction going, but also to be intuitive of when little to no support is necessary. Ways in which the play guide may scaffold interactions include providing explicit direction or modeling play behaviors, offering suggestions or commenting on play, or simply standing nearby the group.

In addition to scaffolding play, the play guide facilitates play interactions by providing social-communication and play guidance. In providing

social-communication guidance, the play guide supports interactions by cueing players to use verbal and nonverbal strategies that facilitate players’ ability to initiate, respond to, join, or maintain play activities (Wolfberg 2003). Social-communication cues provide players with suggestions of what they might do or say during play interactions. For example, in order to initiate play, a child might be cued to tap their peer on the shoulder and say “let’s play” (Wolfberg 2003). Ultimately, the goal is for children to incorporate these strategies into their interactions without assistance from the play guide. Play guidance refers to a hierarchy of techniques designed to involve the novice player in interactions at a level that is just outside of their current skill set (Wolfberg 2003). Types of play guidance range from orienting, in which the novice player is prompted to observe other players, to role playing, in which novice and expert players engage in elaborate pretend play scenarios. In using this series of supports, the goal is that the children will gradually learn how to play together with decreasing amounts of adult support.

Efficacy Information

Several studies evaluating the efficacy of the IPG model describe positive outcomes for children with ASD, including increased social interaction and reciprocal play with peers, increased in the complexity of play (e.g., functional and symbolic play), and decreased in stereotyped and isolated play (Lantz et al. 2004; Richard and Goupil 2005; Wolfberg 1988; Wolfberg and Schuler 1993; Yang et al. 2003; Zercher et al. 2001). Additionally, Wolfberg and Schuler (Wolfberg and Schuler 1993) noted significant gains in language for two out of three participants with ASD, including an increase in the variety of linguistic forms and communicative functions of utterances. Similarly, Zercher et al. (2001) found that all three participants with ASD demonstrated an increase in the number of verbal utterances over the course of treatment. Studies also indicate that skills observed during intervention were maintained when adult support was withdrawn (Lantz et al. 2004; Richard

and Goupil 2005; Wolfberg and Schuler 1993; Yang et al. 2003; Zercher et al. 2001).

Wolfberg and Schuler (1992) conducted a large-scale study investigating teachers' and speech-language pathologists' (SLP) qualitative perceptions of the impact of participation in an IPG on novice players ($N = 38$). Teachers and SLPs reported increases in social reciprocity between novice and expert players and indicated that the IPG provided more opportunities for relationship development than participation in an inclusive setting alone provided. They also indicated that children interacted more naturally in the IPG setting than in other inclusive settings and described the play groups as a "safe haven" for children to play without added outside pressure.

Preliminary evidence exists to support the generalization of skills to settings outside the play group. For example, in a single-subject study Lantz et al. (2004) reported that increases in socially oriented play behavior (e.g., turn taking, sharing, offering or accepting assistance) and common focus play (play characterized by joint attention and social reciprocity) observed during play group were generalized to the classroom. Wolfberg and Schuler (1993) provide qualitative evidence for generalization gained through semi-structured parent and teacher interviews. Results of these interviews indicate that participants with ASD generalized skills gained during intervention to the classroom and home setting.

A major limitation of the aforementioned studies is the small number of participants. Studies providing quantitative measures have ranged from between one and four novice participants. The limited number of participants in these studies limits the generalizability of results. Despite this, evidence to support the utility of the IPG model is promising.

Outcome Measurement

The IPG manual (Wolfberg 2003) includes a series of assessments that are intended to be used throughout the course of intervention:

- *Play Questionnaire* – Completed by individuals who observe the child's play behaviors on a

regular basis (e.g., parents, therapists, teachers) prior to and at the end of intervention. This questionnaire provides information regarding the play experience, preferences, and style of the novice player, along with information regarding their play patterns within a developmental framework. A comparison of pre- and postintervention questionnaires can provide information regarding the child's progress.

- *Play Preference Inventory* – Completed by the play guide prior to the beginning of intervention and periodically over the course of intervention. This inventory is used to record the play preferences of the novice (what they spontaneously choose to do during free play) and how these preferences might connect with the interests of novices players. For example, the play guide might connect a novice player's interest in hair to expert players interests by coming up with an activity where the group pretends they are hairdressers (Wolfberg 2003). A list of ways the novice player's preference can be connected to those of the expert players may be generated during a brainstorming session involving all group members. This inventory assists the play guide in planning activities that will be engaging and enjoyable for all group members and also provides information regarding the novice player's diversity of play, which is later recorded in the *Profile of Individual Play Development*.
- *Integrated Play Groups Observation* – Completed on a weekly basis by the play guide during the first month of intervention and approximately every other week thereafter. This assessment tool provides the play guide with a structured way to complete naturalistic observations of the novice player over the course of intervention.
- *Profile of Individual Play Development* – Completed by the play guide once a month during intervention. This assessment combines information gathered in the aforementioned assessments to provide a complete profile of the novice player for progress-tracking purposes.
- *Record of Monthly Progress in IPG* – Completed by the play guide on a monthly basis during intervention. This assessment tool is

used to chart the novice player's progress in regard to a specific set of individualized goals determined prior to the start of intervention.

Qualifications of Treatment Providers

Training is required to implement an IPG and become a play guide. Individuals who complete this training are typically those who have some experience caring for or working with children with ASD (Wolfberg 2003). To apply IPG principles in an inclusive setting, you must attend a 2-day introductory and intermediate-level training course. The first day of training provides a basic overview of the theory and methods applied during intervention, while the second day concentrates on designing an IPG model for specific children and developing a plan for implementation (Wolfberg 2010). To be qualified to implement the IPG model as a program or service and be qualified as a "master play guide," completion of an apprenticeship program is required. Supervision during the apprenticeship program may be direct or long distance (involving telephone and email conferencing along with exchange of videotapes) depending on the location of the individual (Wolfberg 2010). Certification from the Autism Institute on Peer Relations and Play is provided upon successful completion of this portion of the training.

Definition

Integration in special education refers to the practice of including children with disabilities with their nondisabled peers in the educational setting. Prior to the enactment of IDEA (Individuals with Disabilities Education Improvement Act) in 1975 (then known as The Education for All handicapped Children Act, P. L.94–142), many children with disabilities were segregated from their peers in the educational setting and taught in separate classrooms, separate programs, separate schools, or left at home. IDEA not only mandates a free and appropriate education (FAPE) for all children with disabilities but also includes a mandate, that to the maximum extent appropriate, students with disabilities should be educated with their non-disabled peers (20 U.S.C.1415[5][B]) in what is referred to as the least restrictive environment (LRE). Philosophically, the integration of students with disabilities reflects the effort of educators to create a sense of belonging and acceptance for all students. Educationally, the integration of students with disabilities into the regular education environment reflects the community setting the student will be expected to function in when they leave school. Many professionals continue to disagree regarding the educational benefits of an integrated setting for every student with a disability. The student with special needs right to be integrated in the educational environment with students who do not have special needs (least restrictive environment) must be balanced with the student's right

to an educational environment that is appropriate in meeting his instructional needs.

Short Description or Definition

The definition of intellectual disability (ID) is based on three criteria: (1) significant limitations in intellectual functioning; (2) significant limitations in adaptive behavior as expressed by conceptual, social, and practical adaptive skills; and (3) age of onset before age 18 years (Schalock et al. 2010a). It is estimated that, among people

with autism spectrum disorder (ASD), the occurrence of ID ranges from 25% to 42% (Maenner 2020). Estimates vary due to a number of methodological factors, including the design of the studies, the definitions of ASD and ID, and the ascertainment methods used (LaMalfa et al. 2004; Lecavalier et al. 2011; Matson and Shoemaker 2009; Maenner 2020). ASD is the second most common co-occurring mental disorder in individuals with ID after attention-deficit/hyperactive disorder (AD/HD) (Centers for Disease Control 2010). The diagnosis of ID may be complicated by social communication and behavior deficits inherent to ASD, which may interfere with understanding of and cooperating with assessment procedures.

The authoritative definition of ID is established by the American Association on Intellectual and Developmental Disabilities (AAIDD) Terminology and Classification Committee (Schalock et al. 2010b). A comprehensive psychological assessment is needed to determine whether or not an individual has ID and to tailor a support plan to his or her needs. At a minimum, the assessment must include measures of intellectual functioning and adaptive behavior as well as a history of developmental concerns. Since a diagnosis of ID requires that limitations in intellectual and adaptive functioning have an early onset, specifically before age 18, it is differentiated from other disorders characterized by intellectual and adaptive functioning problems, such as dementia or traumatic brain injury.

Intellectual functioning refers to general mental capacity, which includes the ability to reason, plan, think, and communicate. Intellectual functioning is assessed with a standardized intelligence test, or IQ test. Significant limitations in intellectual functioning are generally considered at or around two standard deviations below the mean of an IQ test. Adaptive behavior is comprised of three skill types:

- Conceptual skills: language and literacy; money, time, and number concepts; and self-direction
- Social skills: interpersonal skills, social responsibility, self-esteem, gullibility, naïveté (i.e., wariness), social problem-solving, and

the ability to follow rules/obey laws and to avoid being victimized

- Practical skills: activities of daily living (personal care), occupational skills, health care, travel/transportation, schedules/routines, and use of the telephone

The following five assumptions are essential in applying the definition of ID and in designing appropriate supports for individuals affected by intellectual disability:

Assumption 1: Limitations in present functioning must be considered within the context of community environments typical of the individual's age peers and culture.

Assumption 2: Valid assessment considers cultural and linguistic diversity, as well as differences in communication, sensory, motor, and behavioral factors.

Assumption 3: Within an individual, limitations often coexist with strengths.

Assumption 4: An important purpose of describing limitations is to develop a profile of needed supports.

Assumption 5: With appropriate personalized supports over a sustained period, the life functioning of the person with ID generally will improve. It is imperative that appropriate supports are identified and provided in order to enhance the individual's functioning, specifically within the areas of development, education, interests, and personal well-being (Schalock et al. 2010a).

Categorization

Adaptive behavior refers to appropriate maturation, learning, and social behaviors required for an individual to function independently and appropriately within one's cultural and age group. For a diagnosis of ID, significant deficits in adaptive behavior are required on a standardized measure normed on the general population, including people with and without disabilities. On these standardized measures, significant limitations in adaptive behavior is approximately two standard deviations below the mean of either (1) one of the

following three types of adaptive behavior: conceptual, social, or practical or (2) an overall score on a standardized measure of conceptual, social, and practical skills. Standardized measures of adaptive functioning are typically informed by parent or caregiver report or, on occasion, self-report. Examples of widely used measures of adaptive behavior include the Vineland Adaptive Behavior Scales (Sparrow et al. 2016), Adaptive Behavior Assessment System (Oakland and Harrison 2015), and the Behavior Assessment System for Children (Kamphaus and Reynolds 2015).

In addition to this criteria, significant deficits in intelligence must be established (at least two standard deviations below the mean) through individually administered, standardized measure of general intelligence. Examples of standardized IQ tests include the Stanford-Binet Intelligence Scales (Roid 2005), Wechsler Intelligence Scale for Children (Wechsler 1991), and Differential Abilities Scales (Elliot 2007). Clinical judgment and expertise are required in the interpretation of information regarding the assessment of adaptive behavior and intellectual functioning and in the formulation of valid diagnoses.

In addition to AAIDD, other widely used classification systems include the *International Classification of Diseases-11* (World Health Organization 2018) and the *Diagnostic and Statistical Manual, 5th Edition* (DSM-5; American Psychiatric Association [APA] 2013). These classification systems each define ID using IQ, adaptive behavior, and age of onset criteria. In addition, the *DSM-5* provides four severity subcategories based on adaptive functioning: mild, moderate, severe, and profound. Both ID and ASD are included under the “neurodevelopmental disorders” category in the *DSM-5* along with communication disorders, AD/HD, specific learning disorder, and motor disorder. The overarching theme of neurodevelopmental disorders is that they originate in early childhood.

There is evidence that the clinical presentation of individuals with ASD varies according to the level of adaptive functioning or

IQ. Level of functioning is negatively correlated with ASD core symptom domains (Buitelaar et al. 1999; Matson and Shoemaker 2009; Munson et al. 2008). In fact, it has been suggested that IQ may be the best predictor of functioning in ASD (Witwer and Lecavalier 2008).

Epidemiology

A meta-analysis of prevalence studies published internationally between 1980 and 2009 found a combined prevalence of ID in the general population to be 10.37 out of every 1000 births (Maulik et al. 2011). The estimated prevalence of ASD in the general population is 62 out of every 10,000 births (Elsabbagh et al. 2012). The determination of an ASD diagnosis may be complicated by genetic conditions that are associated with ID, social deficits, and restricted interests (e.g., Angelman syndrome, Prader-Willi syndrome, fragile X syndrome, Cornelia de Lange syndrome). Individuals with these syndromes may meet criteria for ID and ASD; approximately 12–15% of people with ASD have one of these genetic conditions (Muhle et al. 2004). Genetic testing is needed to diagnose the genetic condition; distinguishing between symptoms of these syndromes and ASD presents additional challenges for clinicians, and in some cases, a child will meet diagnostic criteria for ASD, ID, and a genetic syndrome.

Approximately 75–90% of individuals with ID function with mild impairments, and far fewer (~5%) are impacted to a severe or profound degree. Certain genetic syndromes are associated with severe or profound ID (e.g., Rett syndrome), while other genetic conditions, such as Down syndrome, may be associated with a wide range of intellectual functioning, although usually in the ID range (Jacobson et al. 2008). Males are more likely than females to be diagnosed with both mild (average male/female ratio 1.6:1) and severe (average male/female ratio 1.2:1) forms ID. However, sex ratios vary widely across studies (APA 2013).

Natural History, Prognostic Factors, and Outcomes

Etiology. The etiology of ID is composed of four categories of risk factors (biomedical, social, behavior, and educational) that interact across time, specifically across the life span of the individual and across generations from parent to child. This multifactorial, epigenetic construct replaces prior approaches that divided etiology of ID into two broad types: ID of biological origin and ID due to psychosocial disadvantage. Indeed, biomedical risk factors may be present in persons with ID of cultural-familial origin, and social, behavioral, and educational risk factors may be present in persons with ID that can be attributed to biomedical etiology. It is now estimated that up to 40% of ID are the result of a genetic aberration (Kaufman et al. 2010), though the percentage increases proportionally with severity of ID (McLaren and Bryson 1987). The recommended first-line tests of genetic causes are a chromosomal microarray and fragile X testing (Moeschler et al. 2014).

The increased prevalence of ID in males is largely associated with genetic factors; approximately 40 genes are known to cause ID, and approximately 80% of these reside on the X chromosome. Since males have only one X chromosome, they are less able to compensate for aberrations on the X chromosome associated with these genes than females (Kaufman et al. 2010). This same relationship accounts for the higher prevalence for ASD in males than females (Skuse 2000). According to Harris (1995) and Moser (2004), who studied the prevalence of specific genetic causes of ID in a population of 1,000 births, the 3 most common genetic conditions associated with ID are Down syndrome (1.7), fragile X syndrome (0.5 males, 0.2 females), and Duchenne muscular dystrophy (0.5–1.0). Each of these conditions is characterized by a wide range of physiological and psychological symptoms that manifest themselves within the individual to a varying degree. As such, it is important to note that, although these syndromes are among the leading causes of ID, not all people with these conditions have ID.

ID etiology is based on the interaction of four categories of risk factors across the life span and generations: biomedical, social, behavioral, and educational. The timing of ID etiology is divided into three critical periods: prenatal, perinatal, and postnatal. Table 1 presents these risk factors by category and time period.

Prognostic Factors

Health and Health Care. There is a high risk of health problems among people with co-occurring ASD. Examples include epilepsy, cerebral palsy, hearing and vision impairments, speech-language disorders, and behavioral health problems (Nickel 2000). The prevalence of physical health problems and poor physical health is higher in people with ID compared to people without disabilities (Havercamp and Scott 2015; Young-Southward et al. 2017). Individuals with ID are also susceptible to the primary risk factors of chronic diseases including obesity, decreased physical activity, and smoking. Overall physical health decreases as people with ID age from child to adulthood, and females have been shown to have poorer health than males (Young-Southward et al. 2017). As in the general population, the risk of disease among those with ID increases with age. A study that used a random sample of adults living in the community found that, compared to adults without disabilities, adults with ID were significantly more likely to report being in fair or poor health, more likely to lead sedentary lifestyles, and seven times more likely to report inadequate emotional support. Similar rates of tobacco use and overweight/obesity were reported. Adults with ID had a similar or greater risk of having four of five chronic health conditions compared with peers without disabilities (Havercamp et al. 2004). In addition to these aforementioned health issues, certain etiological conditions are associated with specific health concerns; for example, Alzheimer's disease is especially common in people with Down syndrome (Wisniewski et al. 1985).

People with ASD and ID are at increased risk of exhibiting mental and behavioral health

Intellectual Disability, Table 1 Risk factors for ID

Timing	Biomedical	Social	Behavioral	Educational
Prenatal	Chromosomal disorders Single-gene disorders Syndromes Metabolic disorders Cerebral dysgenesis Maternal illnesses Parental age	Poverty Maternal malnutrition Domestic violence Lack of access to prenatal care	Parental drug use Parental alcohol use Parental smoking Parental immaturity	Parental cognitive disability without supports Lack of preparation for parenthood
Perinatal	Prematurity Birth injury Neonatal disorders	Lack of access to prenatal care	Parental rejection of caretaking Parental abandonment of child	Lack of medical referral for intervention services at discharge
Postnatal	Traumatic brain injury Malnutrition Meningoencephalitis Seizure disorders Degenerative disorders	Impaired child-caregiver interaction Lack of adequate stimulation Family poverty Chronic illness in the family Institutionalization	Child abuse and neglect Domestic violence Inadequate safety measures Social deprivation Difficult child behaviors	Impaired parenting Delayed diagnosis Inadequate early intervention services Inadequate special education services Inadequate family support

problems, which render many at an increased risk of being prescribed more than one medication to address physiological, psychological, and behavioral concerns (Bowring et al. 2017; Sheehan et al. 2015). Individuals with ID are vulnerable to the same adverse effects of medication use as the general population, but these effects may go unrecognized or ignored because the person’s functional limitation may mask or distort the signs, the person’s may be unable to alert caregivers to the symptoms, and because drug-induced movement disorders may be difficult to discern from preexisting stereotypical movement disorders or symptoms of psychiatric disorders or medical problems (Wilson et al. 2004). It is crucial that caregivers are aware of the possible side effects and are equipped with guidelines for monitoring these effects.

Compared to people without disabilities, people with ID face significant disparities in health care and supports. Several factors contribute to these disparities including limited communication

skills, the extra time and skill required to provide quality health care to patients with ID, and the fact that providing care to patients with disabilities is scarcely addressed in medical and other professional school curricula (Iezzoni and O’Day 2006; Kirschner and Curry 2009). A survey commissioned by Special Olympics found that only 25% of medical schools include content regarding persons with neurodevelopmental disorders in their curricula (Corbin et al. 2005). The US Surgeon General released two reports drawing attention to the importance of training health professionals to provide care for people with ID (U.S. Public Health Service 2002), noting evidence that disability confers worse health status and that resources are inadequate to maintain health, prevent secondary health conditions, and optimize wellness (U.S. Department of Health and Human Services 2005).

Mental Health. Individuals with ID are two to four times more likely to experience comorbid mental illness than the general population, with

an estimated 30–40% of people with ID suffering from a psychiatric disorder (Cooper et al. 2007; Einfeld et al. 2011). As with physical health concerns, mental illness can be hard to recognize and diagnose, especially in individuals with limited verbal ability, as the identification of many psychiatric symptoms requires the patient to introspect and self-report internal states. Symptoms of mental health problems are often mistaken for symptoms of ID; this error is referred to as “diagnostic overshadowing.” Furthermore, discomfort from chronic disorders (e.g., constipation), fluctuating pain (e.g., toothaches), or side effects of medication may present to caregivers and clinicians as disruptive or irritable behaviors (Bradley et al. 2007). Recognizing the difficulty in correctly diagnosing mental health problems in people with ID, the National Association for the Dually Diagnosed (NADD) created the *Diagnostic Manual – Intellectual Disability (DMID-2)*; Fletcher et al. 2016), which was designed to accompany *DSM-5*. The *DMID-2* was developed to facilitate an accurate psychiatric diagnosis in persons who have ID and to provide a thorough discussion of the issues involved in reaching an accurate diagnosis. Mental health problems in people with ID are associated with poorer outcomes in major life areas including employment, independent living, quality of life, and health.

Behavioral Health. The presence of ASD and ID have been shown to independently increase the likelihood of engaging in behavioral and emotional problems in children (Totsika et al. 2011), and rates of problem behavior are highest in those with both ASD and ID (McCarthy et al. 2010). Examples of common problem behaviors include aggression, self-injury, disruption, inappropriate sexual behavior, and elopement. The presence of ID can increase risk for developing problem behavior due to the person’s impaired ability to communicate wants and needs or to cope with stressors. Problem behaviors can increase a person’s risk of negative outcomes as they can reduce the person’s access to the community, in particular educational, social, health care, and familial supports.

Outcomes

People with ID are living longer, with life expectancy approaching that of the general population. Because supports for adults with ID are primarily provided by their families of origin, the aging of people with ID becomes a problem for the family and the community. As the parents of adults with ID age, their ability to support their child with the complex care needs associated with having ID and ASD is reduced, particularly if the adult has comorbid physical, mental, or behavioral health needs. This forces families to consider residential placements for their child more frequently than parents were required to in previous generations.

Residential and other support services should be provided in the *least restrictive environment*, that is, a strong preference is given to inclusive settings with peers who do not have disabilities because of the educational and social benefits associated with learning from and interacting with these peers. As part of the US Individuals with Disabilities Education Act (IDEA ca. 1975), the least restrictive environment was identified as one of the principles governing the education of students with disabilities and other special needs. By law, schools are required to provide a free public education in the least restrictive environment that is appropriate to the individual student’s needs. The IDEA is in concert with the movement toward inclusion for people with ID that began with deinstitutionalization in the 1970s and continues today. The least restrictive environment principle guides the provision of residential, vocational, and other community services for adults as well as children with ID and other disabilities. Positive outcomes in terms of health, mental health, and quality of life are associated with self-determination and the availability of social and other supports that meet the individual needs of the person.

Clinical Expression and Pathophysiology

ID is not a disease, a syndrome, or a designation that encompasses a group of medical disorders. It is instead a construct embedded within the

broader construct of disability and descriptions of human functioning. Because of the varied nature and complex interrelated causal processes contributing to ID, it is not possible to succinctly summarize the clinical expression or pathophysiology of the condition. (Please see preceding section “[Natural History, Prognostic Factors, and Outcomes](#),” for more information.)

Evaluation and Differential Diagnosis

Assessment of ID involves systematically collecting information for decision-making and communication related to three assessment functions: diagnosis, classification, and planning individual supports. Within each of these functions, professionals conduct assessments for a variety of specific purposes. For example, a diagnosis might determine an individual’s eligibility for services or legal protection, or it might establish whether a person could be included in a research sample. In order to achieve specific assessment purposes, three criteria must be met: (1) the assessment tools and process should match the purpose for assessment, (2) the assessment findings should be as valid as possible, and (3) the results should be both useful and purposefully applied. Clinical judgment is essential to enhance the quality, validity, and precision of the clinician’s decision and recommendations. Clinical judgment is defined as a special type of judgment rooted in a high level of clinical expertise and experience, and that emerges directly from extensive training, experience with the person, and extensive data (Schalock et al. 2010b). A higher level of clinical judgment is frequently required when the complexity of the person’s functioning or co-occurring disorders precludes standardized assessment.

A diagnosis of ID is made when three criteria are met: (1) significant limitation in intellectual functioning, (2) significant limitation in adaptive behavior, and (3) the onset of limitations occurs before age 18. The terminology of ID has changed frequently (see ► [Mental Retardation](#) entry), yet for the past 50 years, the definition has remained fairly consistent. The American Association on

Intellectual and Developmental Disabilities (2010) defines a significant limitation in intellectual functioning as two standard deviations below the population mean IQ score, equating to a cutoff of 70 or below (plus or minus standard error of measurement). Limitations in adaptive behavior are to be assessed using a standardized measure that has been normed on the general population. Significant limitation is defined as two standard deviations below the mean in the realms of one or more areas of adaptive functioning, conceptual (language, reading, writing, understanding of time and number concepts), social (relating to others, self-esteem, social problem-solving, naïveté, and rule following), or practical (self-care, vocational skills, health care, safety behaviors, use of transportation, technology, and money), or can be determined based on an overall score from all three of these domains. The use of an age criterion distinguishes ID from cognitive impairments that occur at later points in life, such as those associated with traumatic brain injury, mental illness, or dementia. Once a diagnosis of ID is made or suspected, it may be helpful to explore the etiology, as certain genetic conditions have important implications for the health of the individual and for the risk of transmitting an inherited disorder.

Individuals with ID require accommodations to participate in assessments, including psychiatric assessment. Hurley et al. (2003) recommend the following adjustments to a clinical interview: (1) the use of simple vocabulary when interviewing the individual, (2) short, easy to understand sentences, (3) one question at a time, (4) waiting for the individual’s answer before the next question is asked, and (5) the assurance that the individual has complete understanding of the question that is being asked. The examiner must be explicit when clarifying questions due to a more concrete style of reasoning that is commonly displayed by individuals with ID and ASD. Closed-ended (requiring only yes/no answers) or leading questions should also be avoided as they are associated with biased responding. Family members and direct support professionals should also be interviewed for additional information on the individual’s symptoms, especially chronology of

symptom onset, in what environments the problem is observed, and why evaluation is being requested.

Treatment

There is no known cure for ID; however, intervention should be considered at three levels: primary prevention, with the goal of preventing the condition before its biological onset through appropriate prenatal and early childhood care; secondary prevention, which involves early identification and intervention when early signs of ID are identified but before a formal diagnosis is made; and tertiary prevention, the prevention of symptom exacerbation once a diagnosis is made. In the case of ID or developmental delay, tertiary prevention includes early intervention, special education, and finding effective accommodations to help the individual maximize functioning and community participation. This medical model of prevention is more traditionally applied to diseases and physical conditions, yet it offers a helpful context for the various interventions and supports available to people with ID.

Primary Prevention. The goal of primary prevention is to maximize the health of the mother and baby, preventing diseases and conditions, including ID, before their biological onset. Strategies include promoting maternal fitness and healthy nutrition, which can include taking prenatal vitamins with folic acid to promote healthy neural tube development. During pregnancy, women are encouraged to avoid drinking alcohol, using illegal substances, and taking many prescription medications due to the known teratogenic effects on the fetus. Avoidance of drug and alcohol use is especially important, as prenatal exposure to alcohol has been identified as the leading known preventable cause of ID (CDC 2015). After the child is born, primary prevention initiatives include childhood vaccinations against diseases that pose high risks for the baby's life and healthy development. Childhood diseases such as *Haemophilus influenzae* type b (Hib), measles, mumps, and rubella can cause brain inflammation, brain damage, and death in young children. The

safety of childhood vaccinations has been questioned, and an association was claimed between autistic symptoms and vaccines in a study that was later shown to be a deliberate fraud (Wakefield et al. 1998). The Centers for Disease Control and Prevention established a research agenda to investigate safety concerns, which provided overwhelming evidence of the safety of vaccines for infants and young children. This research definitively established that vaccines are not associated with ASD (CDC 2009; see Interagency Autism Coordinating Committee, National Vaccine Advisory Committee). Unfortunately, the now-discredited Wakefield study panicked many parents and led to a sharp drop in the number of children receiving the vaccine that prevents measles, mumps, and rubella. Measles cases have increased dramatically in the ensuing years. Primary prevention efforts to protect children continue throughout childhood and include environmental health initiatives, such as removing lead from paint and gasoline, and public safety initiatives, such as mandating car seats and bicycle helmets to prevent traumatic head injury.

Secondary Prevention. Secondary prevention consists of the identification and interdiction of diseases that are present in the body but that have not progressed to the point of causing signs, symptoms, and dysfunction. Once an individual has been diagnosed with a disease, the emphasis turns to prevent the emergence of symptoms associated with the condition. For example, phenylketonuria (PKU) is a rare condition in which a baby is born without the ability to properly break down the amino acid phenylalanine. Untreated, PKU is associated with delayed mental and social development, hyperactivity, seizures, and severe intellectual disability. These impairments can be completely avoided when a special diet that is extremely low in phenylalanine is followed. Most states require a PKU screening for all newborns so that treatment can begin immediately.

Tertiary Prevention. Tertiary prevention consists of the preventing disease progression, rehabilitation, and reducing the sequelae of the condition. Services are provided to reduce the number, extent, and severity of direct or indirect side effects associated with the identified condition. For example,

early intervention will enhance the development of young children already exhibiting developmental delays (of known or unknown etiology) both by altering their developmental trajectories and by preventing secondary complications from occurring. For children at risk of ID because of a variety of biological and/or environmental conditions, it is expected that these delays can be prevented entirely or their magnitude minimized through early intervention services (Guralnick 2005). Common services that are funded by federal and state entities include specialized preschool services, special education programs throughout elementary, middle, and high school, and, for young adults, programs to assist in the transition from a high school to a vocational setting. For children with ID who have specific behavioral health concerns, parent training and behavior support services are commonly recommended and used. Individual and group psychotherapy can be helpful in treating behavioral health conditions in children and adults with ID (NICE 2017; Schalock et al. 2010a). Peer support groups are organized for adults with ID to provide and receive social and emotional support, as well as skill building. Adults with ID benefit from job training and case management services to improve employment and community living outcomes. Numerous advocacy groups have also been organized across the United States and other countries to promote equal rights and opportunities for all individuals with ID (United Nations 2006).

For adults with ID and ASD, individual service plans are centered on the individual's interests and goals and focused on providing supports and services to promote overall well-being. Plans are intended to adopt a dynamic, life span approach, with the emphasis on continuous revision of goals to meet the individual as he or she progresses through life. Treatment plans strive to address multiple aspects of life, including self-care skills, social skills, education, and physical, mental, and behavioral health. Self-determination skills are commonly addressed in treatment plans including self-awareness, self-advocacy, self-efficacy, decision-making, independent performance, self-evaluation, and adjustment that contribute to an individual's ability to establish and achieve his or her own goals.

Definition

This term has been used to characterize aspects of the ways in which more able individuals on the autism spectrum, particularly those with Asperger's disorder, cope with their difficulties in empathy and perception of the feelings of others. Asperger (1944) emphasized this as one aspect of the clinical presentation of the latter condition, and subsequent investigators (e.g., Klin et al. 2005) have also underscored this unique approach to understanding other people's feelings.

The concept represents an extension of the more general notion of intellectualization as a defense mechanism, that is, for the more typical population the approach to thinking about troubling situations or anxiety-laden issues may help provide some distance from the experience of unpleasant affects. Although prefigured, as a more general concept, by Sigmund Freud, it was his daughter Anna who elaborated the more specific concept and noted its developmental correlates.

Individuals with Asperger's engage in various approaches to coping with the problem of understanding other people's feelings and intentions. In their often somewhat professorial style, they may try to "decode" the feelings of others by approaching the problem in a highly intellectual, as opposed to more empathic, way. When carried to an extreme, this approach can take the form of

mathematical modeling of people's affective states.

Intelligence Norms

Shirley Poyau

Clinical Psychology, University of Massachusetts Boston, Boston, MA, USA

Definition

Intelligence is generally assessed using "norm-referenced tests," which evaluate test-takers not on their absolute performance but on their relative ranking compared to the scores obtained within a predetermined population, most often a nationally representative sample of same-aged peers. Individual scores represent how much better or worse any single person scores relative to the average. Norms can be generated for tests that are standardized or are administered in a consistent

manner to all individuals who take the test. Most often, an individual's performance in relation to the norms are provided in the form of a standard score, which has a mean of 100 (average) and a standard deviation of 15. Beginning in the early twentieth century, it was noted that raw scores on intelligence tests have consistently risen over time, so that the average score at any given time is significantly higher than the average had been several years before. This phenomenon is known as the Flynn Effect, a term coined in the book "The Bell Curve" by authors Richard Herrnstein and Charles Murray. It was named after James R. Flynn, who first documented the effect. Every few years, intelligence tests must be updated and re-normed so that the scores obtained truly reflect an individual's performance with respect to the rest of the population at that time.

Recent studies have suggested the intelligence tests may not accurately capture and may underestimate the abilities of individuals with Autism Spectrum Disorder (ASD). Children with ASD were found to score significantly higher on a test measuring "fluid intelligence", which involves novel problem-solving skills such as task management, understanding rules, and mental abstraction, than they did on the Wechsler Intelligence Scale for Children (WISC IV), which is thought to be heavily reliant on language skills and previously learned information (► [Crystallized Intelligence](#)). Typically developing children tended to score equally well on both tests.

Synonyms

[IQ](#)

Definition

Intelligence quotient, abbreviated IQ, was originally the ratio of mental age to chronological age. The term "mental age," popularized by early tests of intelligence, referred to the age of the children in the standardization sample whose performance the testee matched. Most tests of intelligence no longer use this ratio, and IQ instead refers to a person's ability relative to available norms, which are usually age-based. By convention, IQ scores are designed to have a mean of 100 and a standard deviation of 15. Thus, about 95% of people fall within two standard deviations of the mean (i.e., 70–130). Norm-referenced scores have decreased reliability at extreme values; for this reason, most tests do not provide scores more than four standard deviations away from the mean (40–160). Giftedness is sometimes defined as scores more than two standard deviations above the mean. Intellectual disability is defined based on both IQ and adaptive behavior; however, the current Diagnostic and Statistical Manual (APA, 2013) no longer classifies intellectual disability into levels based on IQ. Within the ASD literature, the terms "low functioning" and "high functioning" are sometimes used to denote IQs below 70 and above 70, respectively, though there is no empirical rationale for this practice. Although IQ and "intelligence" are often used interchangeably,

IQ represents intelligence as defined by performance on a specific test.

ITS

Description

The Interactive Trauma Scale (ITS) is an interactive touchscreen self-report measure of childhood trauma symptoms, administered via touchscreen tablet or smartphone, for children and youth with autism spectrum disorder (ASD). The measure is designed for use with children ages 6–14. Items are read aloud by the examiner as needed. Eight trauma exposure items ask about traumatic and adverse experiences. These are followed by 22 symptom items congruent with DSM-5 criteria for posttraumatic stress disorder (American Psychiatric Association 2013) and 7 neutral items (e.g., “I like dinosaurs”) interspersed to maintain the child’s engagement and comfort. Children respond via a 5-point thermometer-like scale rated from “Never” to “Always.”

History

This screening measure originated from a clinical need to obtain firsthand child and adolescent input in mental health assessments following suspected abuse, neglect, peer victimization (see ► [“Peer Victimization”](#)), and other potentially traumatic events. Children with ASD are frequently exposed to potentially traumatic and other adverse experiences, though posttraumatic stress disorder (PTSD) in this population is only beginning to be studied. Current evidence indicates that children

with ASD are more likely than other children to be abused or maltreated or to be victims of bullying than nondisabled children, their own siblings, and peers with other disabilities (Maïano et al. 2016; McDonnell et al. 2018; Zeedyk et al. 2014). They are also more likely than their typically developing peers to experience adverse childhood experiences such as household mental illness and substance abuse, income insufficiency, parental divorce, and neighborhood violence (Berg et al. 2016; Kerns et al. 2017). Following traumatic events, identifiable symptoms of anxiety, depression, PTSD, regression in adaptive behavior, and suicidality are evidenced in youth with ASD (Bleil Walters et al. 2013; Mayes et al. 2013; Mehtar and Mukaddes 2011; Valenti et al. 2012).

Complicating the assessment of trauma symptoms in children and youth with ASD are associated communication deficits, emotion regulation difficulties, and multiple co-occurring psychiatric problems (Matson and Cervantes 2014). A PTSD diagnosis in youth with ASD may also be missed or overlooked due to “diagnostic overshadowing” in which assessors inaccurately attribute challenging behaviors or anxiety to the ASD itself (Kerns et al. 2015; see ► “Diagnostic Overshadowing”). Likely because of their core deficits in communication, emotional understanding, and expression, children with ASD show differences from typically developing children when asked to report psychological symptoms on behavior rating scales (Mazefsky et al. 2011; Mahan and Matson 2011). On self-report measures, they tend to self-enhance relative to typically developing peers, fail to complete measures, or interpret items in an overly literal manner, though there is evidence that higher functioning youth with ASD show no less self-awareness than typically developing youth (Schriber et al. 2014). Clinicians have come to rely on the reports of parents or other observers for this purpose (Mahan and Matson 2011). However, there is much evidence that even parents of typically developing, emotionally expressive children often rate them much differently than children rate themselves on a variety of measures (Renk and Phares 2004). Child and adolescent self-reports have been shown to add significantly to the diagnostic picture in ways that are

unique and not accounted for by observer reports (Adams et al. 2014).

Treatment providers and educators have increasingly turned to electronic touchscreen platforms including tablets, smartphones, and computers to present material to children with ASD (see ► “Computer-Assisted Instruction to Teach Academic Skills”). Some of these programs have been shown to effectively engage children with ASD for education and treatment in increasingly effective ways (Neumann 2018).

Psychometric Data

During the initial creation of the ITS prototype, graphics and response features were programmed and then posted for review on an online beta testing site ([Testing.org](https://www.testing.org)). The prototype was then reviewed by a group of eight clinicians familiar with both autism and trauma in children. The original versions were improved based on feedback by the reviewers by adjusting the questions and the graphic design to enhance understanding and to provide unambiguous representation of trauma-related stimuli. These changes were incorporated into a revised version of the prototype for psychometric analyses.

Trauma exposure items for the prototype were selected based on commonly reported experiences in youth that are similarly tapped in other scales such as the UCLA Posttraumatic Stress Disorder Reaction Index (UCLA-PTSD-RI; Steinberg et al. 2013). Children are asked whether or not they have had physical neglect experiences, were “bullied or hurt by other kids,” witnessed “bad or scary things like someone getting hurt,” “hit or hurt by an adult,” touched by someone on “your private parts or get you to touch their private parts,” “teased or called mean names,” “in a natural disaster like a hurricane or earthquake,” and lost someone “because they died or went away.” Questions about exposure to bullying and teasing are included because of the high frequency of such experiences in children with ASD.

Symptom items for the prototype were written to assess each of the five DSM-5 PTSD criterion domains (American Psychiatric Association

2013): intrusion symptoms (e.g., “I have bad dreams”), negative mood (e.g., “I am no good”), dissociative symptoms (e.g., “I feel like things aren’t real”), avoidance (e.g., “I try to stay away from people, places or things that remind me. . .”), and arousal symptoms (e.g., “I do things that are not safe”). The measure is scored by summing Likert scale ratings of 3 (moderate level rating) and above in each criterion area. Respondents are judged to screen positive for PTSD symptoms when at least one exposure item is endorsed and one or more symptom item is endorsed in each of the intrusion and avoidance domains, with two or more in the arousal and negative mood domains, consistent with DSM-5 criteria.

User Satisfaction

In a recent validation study (Hoover and Romero 2019), participant ratings were highly positive: 81% rated it as easy or very easy to use; 74% rated it as comfortable and understandable or “very much” so, and 76% rated it as effectively facilitating identification of feelings. The overall experience was rated as “good” or “really good” by 88% of participating children.

Validity and Reliability

Children’s endorsements of traumatic exposures on the ITS were moderately correlated with their responses to similar items on the UCLA Post-traumatic Stress Disorder Reaction Index-Self Report (UCLA-SR; $r = 0.554$; $p < 0.05$) and UCLA parent report form (UCLA-PR; $r = 0.638$; $p < 0.01$). The item “teased or called mean names” was the most frequently endorsed (75%) on the ITS, followed by “bullied or hurt by other kids” (70%). Death/loss of a loved one (65%) and witnessing “bad or scary things like someone getting hurt” (50%) were also frequently endorsed.

Overall, the ITS and UCLA-SR trauma symptom severity ratings were strongly correlated ($r = 0.782$; $p < 0.01$) with lower correlations between the ITS and UCLA-PR ($r = 0.223$) and between the UCLA-SR and UCLA-PR ($r = 0.314$). Table 1 presents Pearson’s r correlations between ratings on items of similar content across the three measures. Of the 19 individual

* $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$

item comparisons between the UCLA-SR and ITS, 13 were moderately to strongly correlated. These include the following items: scared/afraid ($r = 0.514$; $p < 0.05$), amnesia ($r = 0.549$; $p < 0.05$), feelings of being “no good” ($r = 0.620$; $p < 0.01$), diminished closeness with others ($r = 0.622$; $p < 0.01$), feeling angry ($r = 0.682$; $p < 0.01$), self-blame/guilt ($r = 0.697$; $p < 0.01$), difficulties with attention

and concentration ($r = 0.748$; $p < 0.001$), and sleep disturbance ($r = 0.785$; $p < 0.001$).

Five (25%) of the participants screened positive for PTSD diagnosis on the ITS as they endorsed the requisite symptoms in each DSM-5 criterion area. These participants reported an average of 6.2 trauma exposure types (SD 2.925) and all of them endorsed experiences of bullying and teasing victimization. Those who did not screen positive for PTSD on the ITS reported experiencing fewer types of traumatic events ($M 3.80$; $SD 1.707$; $t = 2.06$, $p < 0.05$). PTSD-positive screening youth had higher overall frequency scores on the ITS ($M 62.40$; $SD 11.876$) than those who did not screen positive on the ITS ($M 41.53$; $SD 14.366$; $t = 2.78$, $p < 0.05$). Three of the five participants also screened positive for PTSD on the UCLA-SR and four on the UCLA-PR. Age-adjusted PVT scores were essentially uncorrelated with overall symptom frequency ratings on the ITS ($r = 0.187$). Internal consistency reliability was assessed using Cronbach's coefficient alpha ($\alpha = 0.855$), suggesting adequate internal consistency of the ITS symptom items.

Clinical Uses

The ITS employs a tablet or smartphone-based touchscreen delivery method meant to engage children with autism in order to obtain their self-reports of potentially traumatic events and symptoms. Touchscreen devices are popular and familiar to children with ASD and may facilitate screening and assessment in community and treatment settings, for initial identification of trauma, and referral for more comprehensive trauma evaluation.

The measure shows initial evidence for usefulness and reliability in clinical mental health settings with children and youth ages 6–14 who have ASD and suspected exposure to trauma. Given the paucity of studies and lack of trauma measures designed for use with children who have developmental disabilities, the ITS provides a potentially readily accessible screening format that has been

previously unavailable. Besides being a useful clinical tool, including firsthand reports from youth about their traumatic experiences rounds out a complete assessment to help answer as-yet unanswered questions about ASD and PTSD. For example, current research does not clarify whether children with ASD show similar symptoms to their typically developing peers (Hoover 2015). Some argue that children with ASD may be either more or less sensitive to traumatic experiences. Such sensitivity may depend on the child's overall level of adaptive functioning, emotion regulation, and attentiveness to potentially traumatizing information about their surroundings (Kerns et al. 2015).

The ITS asks specifically about peer victimization and its effects, an aspect that is missing in most extant childhood trauma measures. A history of physical and verbal bullying was reported by most of the validity sample (Hoover and Romero 2019) and is commonly reported by children with ASD. As serious negative mental health outcomes have been shown to arise from bullying, especially among youth with ASD (Zablotsky et al. 2013; Mayes et al. 2013), these youth tend to report differently about their victimization experiences than their caregivers, such assessment data is especially needed. Effective treatment of challenging behaviors, anxiety, and regression in adaptive functions will necessarily incorporate an understanding of children's trauma exposures and symptoms.

Synonyms

Collaborative teaming model; Individualized education program (IEP) team; Individualized family services plan (IFSP) team; Multi-disciplinary team; Planning and placement team (PPT); Transdisciplinary team

Definition

An interdisciplinary team is a group comprised of specialists from multiple and varying backgrounds or fields and/or individuals with expertise or extensive knowledge about the individual, topic area, object, or other unit of analysis, for purposes of combining skills, resources, and information that will guide decisions and practices concerning the focus of study. Teams can be formed in health care, educational, counseling, and other settings concerning the needs of individuals with autism spectrum disorders. In cases of supports and services in educational settings for those with ASD from birth through 21 years of age, members of the planning and placement team (PPT) or IEP team, individualized family services plan (IFSP), and individualized education program (IEP) teams conduct, interpret, and present findings from evaluations conducted independently to the entire group for purposes of cooperation and collaboration in developing programs and planning instruction jointly for children with disabilities. From comprehensive assessments conducting in the medical setting to those included as part of a comprehensive evaluation process for special education eligibility determinations, an interdisciplinary team is necessary for providing the expertise in understanding outcomes, interpreting results, and educating other

team members on how to translate findings into practice and interventions. Since autism spectrum disorders affect multiple developmental domains, utilizing an interdisciplinary team constitutes best practice for a diagnosis of ASD and is an essential component of the assessment process as well as developing and implementing intervention plans. An interdisciplinary team promotes communication among team members and leads to a more integrated, cohesive translation of findings. A quality interdisciplinary process involves individual contributions to inform the construction of the overall picture of the individual with ASD; individual interpretations enable formulation of conclusions and recommendations based upon the combined efforts of the team.

Definition

Interests characterized as “circumscribed” are included in the diagnosis of autism within the general area of restricted and repetitive behaviors

(RRBs). For example, in sign B3, DSM-5 describes “highly restricted, fixated interests that are abnormal in intensity or focus” and provides as examples “strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interest.” Unusually focused, intense, and persistent interests in autism may feature the amassing of large quantities of information and resistance to any diversion from their pursuit (Boyd et al. 2007). Importantly, what are called circumscribed interests in autism are associated with positive emotions and the potential for great satisfaction, thus contrasting with obsessions and compulsions, which are dreaded and troubling (Klin et al. 2007).

Pinpointing the concept of circumscribed interests and distinguishing it from related signs included in the general RRB area is however not easy. Indeed, the delineation between circumscribed interests and other RRB DSM-5 diagnostic signs is somewhat uncertain and arbitrary, with apparent redundancies and overlap across development. For instance, repetitive use of objects (sign B1) may be a form of attachment to or preoccupation with those objects (sign B3), as may be unusual interest in sensory aspects of the environment (including objects; sign B4). Highly restricted, fixated interests (sign B3) and stereotyped motor movements (sign B1) may both be described externally as insistence on sameness and inflexible adherence to routines (sign B2). Further, the word “interest” implies some kind of seeking behavior and positive emotions. Repetitive motor movements or lining up toys (sign B1) and visual fascination with lights or movement (sign B4) may be associated with positive emotions as well. In that sense, the distinction between, for example, persistently seeking out ceiling fans and looking laterally and happily to them, and the same behavior applied to finger movements, is arbitrary and both could be encompassed under circumscribed interests (sign B3).

Other divisions or subgroupings of RRBs have also been proposed. In the Autism Diagnostic Interview (ADI), circumscribed interests are distinguished from “unusual preoccupations.” The latter focuses on the odd or peculiar quality of the interest (e.g., ceiling fans), whereas the former

are also found in the nonautistic population (e.g., hockey statistics) but with different qualitative properties. The autistic quality of an autistic interest is related to its circumscribed nature, degree of focus, overtly or relatively nonsocial quality, and atypical progression over time, as well as to its being at odds with developmental level or context (Lord et al. 1994).

Another subgrouping of the RRB area attempts to distinguish “low-order” behaviors characterized by repetition of movement, associated with lower developmental levels and “simple” behaviors (e.g., gestural stereotypies), from “high-order” behaviors, associated with higher developmental levels and more complex behaviors (e.g., circumscribed interests; Turner 1999). However, both high-order (DSM-5 signs B2, B3) and low-order (signs B1, B4) behaviors share the qualities of interest and focus. This is why some studies collapse verbally/abstractly (circumscribed interests) and nonverbally/concretely (unusually strong attachment to certain objects or parts of objects) defined focused interests, independently of the verbal capabilities of the individual and his developmental level.

Historical Background

In Kanner’s first descriptions, the notion of circumscribed interest is present in the form of intense focus, expressed as repetition and insistence on sameness: “The repetitiousness assumes the form of obsessive preoccupations” (Kanner 1943). It is also positively described as an “excellent, purposeful, and intelligent relation to objects that do not threaten to interfere with their aloneness.” Robinson and Vitale (1954) independently described three individuals under the title “Children with circumscribed interest patterns” and emphasized precocity in knowledge as well as deleterious effect of interests on typical relationships with peers. Kanner’s first use of the term “circumscribed interests” was in his commentary on Robinson and Vitale’s work.

In 1980, the DSM-III description of autism included one mandatory RRB criterion: “Bizarre

responses to various aspects of the environment, for example, resistance to change, peculiar interest in or attachments to animate or inanimate objects.” The expanded 1987 DSM-III-R multiple-item RRB domain included both “persistent preoccupation with parts of objects” and “markedly restricted range of interests and a preoccupation with one narrow interest.” In 1994, this carried over into the DSM-IV attempt to distinguish implicitly verbal interests from concretely defined, implicitly nonverbal interests. Finally, the 2013 DSM-5 added a “sensory” component to the RRB area, encompassing unusual sensory interests.

Current Knowledge

Empirical Findings

A growing body of descriptive knowledge documents the range of autistic interests. In a retrospective compilation of Asperger’s clinical case records, of 44 children diagnosed with “autistic psychopathy” for whom information was available, 82% had “special, original and narrow interests” (Hippler and Klicpera 2003, p. 297; see also Klin et al. 2007, as well as Gilchrist et al. 2001, for similar findings). For 33 of these children, domains of interest were categorized as animals and nature (30%), technical and/or scientific interests (27%), obsessive reading/collecting facts (24%), public transport systems (18%), religion (12%), drawing (12%), music (9%), and space/astronauts (6%). Specific unusual interests included eye muscles, rubbish bins, earthworms, and “inventing own methods for calculation.”

An investigation among the parents of 61 autistic individuals indicated that the most frequent materials or areas of information involved in circumscribed interests were Japanese animation and cartoon characters, electric and mechanical apparatus, dinosaurs, space/physics, natural disasters, historical events, encyclopedias/fact books, videogames, technical manuals, religion or politics, reptiles, rodents, printed material in general, television in general, and facts (South et al. 2005). In a survey of 92 parents, “obsessional interests” in autistics were reported in broad categories

including physics (84%), taxonomy (73%), and TV/audio (64%; Baron-Cohen and Wheelwright 1999). Another survey conducted among the caregivers of a large population of fluently speaking autistic individuals revealed that circumscribed interests frequently involve memorization of facts expressed verbally, including an early interest in letters and numbers (Klin et al. 2007). Eight categories of activities were observed, including two types of fact collection, verbal memory (e.g., naming makes/models of cars) and visual memory with associated activities (e.g., making LEGO dragons). The remaining six categories were sensory behaviors (e.g., lining up objects), math (e.g., naming prime numbers), ordering information (e.g., classifying insects), dates and time (e.g., memorizing birthdays), hoarding (e.g., collecting Frisbees), and letters/numbers (e.g., decoding).

Circumscribed interests may change with development, from early interest for parts of objects (Gilchrist et al. 2001; Richler et al. 2010) and letters and numbers (Ostrolenk et al. 2017) to more complex interests in older individuals (Klin et al. 2007). When longitudinal data are available, this gradual increment is evident even at the individual level (South et al. 2005). The birth of circumscribed interests is understudied but in some cases can be traced back to a unique encounter with a specific material (e.g., Mottron et al. 2006). Circumscribed interests are also associated with higher apparent IQ (Bishop et al. 2006), as well as with typical or precocious speech development, although this may trivially depend on the overlap between the definition of circumscribed interests and speech abilities (Lam et al. 2008). Specificity toward intellectual disability is high (Bodfish et al. 2000), but not toward exceptional typical individuals, at least when it comes to importance of personal investment and association with higher intelligence (DeLoache et al. 2007).

Although never studied in a systematic way, circumscribed interests seem highly associated with savant abilities, given that any reported savant ability involves a circumscribed interest in the relevant domain (Young 1995). Interest can be ascertained through overt interacting behaviors with a specific material. These

behaviors result in the cognitive manipulation of units composing this material, which favors a “frequency effect,” that is, the faster recognition and stronger memorization of the material involved in the savant ability (Mottron et al. 1996). In this sense, focused intense (ergo “circumscribed”) interests may represent the autistic equivalent of the ensemble of behaviors and cognitive modifications associated with *expertise* in nonautistics.

Adaptive properties of circumscribed interests are considered in contrasting ways among researchers. Circumscribed interests may represent the ways in which autistics learn well (Dawson et al. 2008) and are associated with positive emotions across the lifespan (Mercier et al. 2000; Smerbeck 2017). They constitute a heuristic tool to understand the world (Klin et al. 2007), foster skill development and communication (Winter-Messiers 2007), and become the foundation for higher education and employment in adulthood (Patten-Koenig and Hough-Williams 2017). Conversely, they may be regarded as behaviors which require the largest accommodation in parents of autistics (Gabriels et al. 2005), and most interfere with other activities: a large portion of an autistic’s free time is overtly dedicated to their intense interests. The extent to which such interests are judged as “interfering” in preschool and early school years predicts Vineland adaptive behavior scores later in adolescence (Klin et al. 2007).

The overlap or autonomy of circumscribed interests with or toward other RRBs in autism can also be studied through factorization of ADI RRB items, although the relative lack of precision of this tool for the repetitive area limits the informative value of these studies. Whereas factorization studies among RRBs consistently oppose a “repetitive sensory and motor behaviors” factor to an “insistence on sameness” factor, circumscribed interests stand as a distinct factor (Lam et al. 2008) and do not correlate with participant characteristics, supporting its conceptual autonomy.

Neurobiological counterparts of circumscribed interests are found in studies of genetics and brain functioning. Circumscribed interests are partially shared by parents in the form of intense

preoccupations (Hippler and Klicpera 2003; Smith et al. 2009). Involvement of the amygdala when an autistic interacts with the subject of a circumscribed interest has been demonstrated through fMRI (Grelotti et al. 2005). In the case of hyperlexia, a label which groups focused interest in written materials with exceptional abilities in decoding text, autistic expertise is associated with a functional cortical rededication of brain areas involved in reading (Turkeltaub et al. 2004). An involvement of synesthesia has also been suspected in the choice of domain of interest as well as on the nature of mental manipulation operations performed on this material (Motttron et al. 2013).

Theoretical Accounts

There is agreement on the fact that RRBs have a certain kind of etiological and phenotypical autonomy from sociocommunicative behaviors in autism, preventing a straightforward explanation of one by the other (Happé et al. 2006; Richler et al. 2010). Their relative magnitude is not correlated according to current measures, while their distribution in the general population and their developmental profile differ. Available theoretical accounts of circumscribed interests include those which do or do not posit a causal deficit. One account originated with the overt resemblance between perseveration in frontally injured patients and the constancy autistics demonstrates in the pursuit of their circumscribed interest. This led to the proposal of an executive dysfunction account of circumscribed interests (Turner 1999). However, autistic individuals do not consistently display impairments in classic executive tasks, which questions how “executive” the purported deficit is.

Other accounts of circumscribed interests invoke the atypical strength or hyperfunctioning of a cognitive substructure. Two models hypothesize that atypical perception – understood as resulting from diminished top-down processes (weak central coherence; Happé and Vital 2009) or as enhanced perceptual functioning (Motttron et al. 2009) – is involved in the nature and processing of materials which are the object of autistic interests.

According to the EPF model, intense focused interests are the behavioral and cognitive counterpart of enhanced pattern detection and manipulation along autistic development. This is manifested, among other behaviors, by a spontaneous orientation toward genuine regularities loading a domain of interest. Materials involved in circumscribed interests, as well as in savant syndrome, often consist of ubiquitous human codes (e.g., written language in various formats, music, numeration, and three-dimensional graphic representations) rich in regularities across multiple scales, from simple units to overarching structures. Thus, there may be veridical mapping between isomorphic structures through pattern detection mechanisms, which are especially active in autism. In another account, autistics are characterized by *hypersystemizing*. Systemizing is described as detecting and applying strict, inflexible rules or laws, such as those of “if p, then q” form (Baron-Cohen et al. 2009). Narrow or circumscribed interests thus result from the rigidity of hypersystemizing. Whatever the model, there is in the last decade a belated trend toward envisioning circumscribed interests more accurately in autism research, for the benefit they bring to the well-being of the person. This includes preliminary steps toward studying how autistic interests may be harnessed in early intervention, in education, in employment, and in finding a social niche.

Conclusion

The importance of what are called circumscribed interests in autism research, and their appreciation as a major organizer of quality of life for autistics, has fluctuated over the years. However, the area as a whole remains understudied relative to its importance to both autistic and nonautistic individuals and relative to its potential to cast a light on the fundamental nature of autistic cognition. More accurate, less pathologized, and less biased views of autistic interests also offer new perspectives for the integration of autistic people in a modern and open society.

Future Directions

- What role does availability of information play in the development, nature, narrowness, and outcomes of autistic interests?
- To what extent and under what circumstances are autistic interests truly restricted or circumscribed?
- Under which circumstances do autistic interests lead to very good or exceptional outcomes?
- Is there a critical period for intense focused interests in autism, or can they develop across the autistic lifespan, given the opportunity?
- Does the presence or absence of speech delay modify the nature and course of circumscribed interests in autism?
- What is the association between circumscribed interests and the acquisition of literacy in autistic individuals?

Internalization of Emotion Co-regulatory Support in Children with ASD

Jason K. Baker, Rachel M. Fenning and Jacquelyn Moffitt

Department of Child and Adolescent Studies,
California State University, Fullerton, Fullerton,
CA, USA

Adaptive emotion regulation involves the ability to understand, monitor, and modify internal states in order to achieve one’s goals (Thompson 1994). Although infants demonstrate certain behaviors thought to assist with the regulation of arousal (e.g., gaze aversion, thumb-finger sucking), it is generally agreed that very young children are primarily “co-regulated” by their caregivers (Cole et al. 1994; Kopp 1982). Over the first few years of life, more direct co-regulation (e.g., responsive comforting, instrumental support, emotion contagion) gradually gives way to parental efforts aimed at helping children become more autonomous in their regulatory abilities (Cole et al. 1994; Grolnick and Farkas 2002; Kopp 1982; Morris et al. 2007). Although more general patterns of parent or family behavior continue to contribute to the development of children’s emotion regulation throughout childhood, parents increasingly engage in more didactic socialization strategies, such as intentional modeling and what

is commonly referred to as either emotion “coaching” or “scaffolding” (Baker et al. 2011; Gottman et al. 1996; Morris et al. 2007).

Parental environments characterized by responsive involvement, sensitive structuring, and support for child autonomy are conceptualized as facilitating a shift from external co-regulation to internal regulatory control (Grolnick and Farkas 2002), with parenting contributing critically to underlying biobehavioral processes (Beauchaine et al. 2007; Cole et al. 1994). Internalization of co-regulatory supports is suggested when a child begins to demonstrate autonomous use of strategies or competencies that were originally promoted in the context of external (e.g., parent) support (Baker et al. 2019; Cole et al. 1994; Grolnick and Farkas 2002; Kopp 1982). Theoretical accounts of internalization processes related to the regulation of emotion suggest that great strides in self-regulation occur during the preschool years (Cole et al. 1994; Kopp 1982). Although clear empirical evidence for age markers related to the development of emotion regulation in children is lacking, it is generally assumed and expected that most children demonstrate a reasonable level of self-regulation by middle childhood (Cole et al. 1994).

Children with autism spectrum disorder (ASD), as a group, experience considerable difficulty in regulating their emotions, as demonstrated by higher levels of behavior indicative of emotion dysregulation, use of fewer strategies presumed to be helpful for regulation, and reduced effectiveness of such strategies as compared to peers with neurotypical development (Jahromi et al. 2012; Samson et al. 2015). The longitudinal course of the development of emotion regulation in children with ASD requires empirical study. However, it is clear that many children with ASD continue to exhibit significant emotion dysregulation well into the elementary school years (e.g., Fenning et al. 2018; Jahromi et al. 2012) and at least one cross-sectional study did not find lower dysregulation as a function of higher child age in a sample of 4- to 11-year-olds with ASD (Fenning et al. 2018). This apparent delay in the development of autonomous

regulatory competence in children with ASD may be accompanied by (or potentially a product of) a delay in the internalization of caregiver co-regulatory support. Indeed, Ting and Weiss (2017) did not find any association between parent-child discussion and regulation strategies generated independently by school-aged children with ASD. Fenning et al. (2018) reported that parental co-regulatory scaffolding was related *in the moment* to the quality of their children’s emotion regulation during a frustrating task, but that scaffolding was not significantly associated with individual differences in children’s regulation during an *independent* task, suggesting effective co-regulation but the absence of internalization of the support.

The cross-sectional data from Fenning et al. (2018) were re-analyzed to specifically address age differences in the apparent internalization of co-regulatory support. Baker et al. (2019) hypothesized that increased internalization would be observed at higher child ages, as indexed by stronger consistency in dysregulation scores across parent-child and independent child tasks and a stronger inverse association between parental scaffolding during the dyadic task and child dysregulation during the independent task. Indeed, higher consistency across tasks was observed for the older as compared to the younger children in the sample of children ages 4–11 years. In addition, the association between parental scaffolding and children’s independent dysregulation became increasingly negative at older child ages; however, even at the higher ages, the association was only significant at a trend level, suggesting that internalization may not be observed until late childhood or even early adolescence in children with ASD.

While the apparent internalization of co-regulatory supports in children with ASD may depend upon child chronological (but perhaps not mental) age (Baker et al. 2019), the mechanisms accounting for this potential group delay or individual differences in the development of these processes remain unknown. Neurodevelopmental differences associated with the core features of ASD (e.g., reduced social awareness, cognitive and behavioral inflexibilities) are

thought to contribute significantly to the regulation difficulties experienced by these children (Fenning et al. 2018; Mazefsky and White 2014) and may similarly impact relevant internalization processes. Although environmental factors are unlikely to account for the status-group difference, certain parenting behaviors may contribute to individual differences in internalization processes within this population. For example, Hirschler-Guttenberg et al. (2015) reported that maternal authoritarian parenting was associated with limited seeking of parental co-regulatory support in preschoolers with ASD.

There is clear evidence that children with ASD, as a group, experience difficulties in their ability to regulate emotions. What is desperately needed is information relating to the developmental course of emotion regulation in these children, including the identification of not only what might promote beneficial trajectories but also when and how these influences contribute. The apparent lack of concordance between parent co-regulatory support and children's independent regulatory competence during the early school years is concerning, and, should these early findings be replicated, understanding the degree to which alternative parenting behaviors or scaffolding supports are beneficial as children with ASD age may be key to intervention efforts aimed at promoting regulatory competence in this population.

- Spending too much time video gaming with others
- The obsessive collecting of data and images

Internet Safety

Sheree Incorvaia
Vocational Independence Program, New York
Institute of Technology, Central Islip, NY, USA

Definition

The Internet has provided people around the world with opportunities to find information and to meet people at the click of a button. Studies have even shown that use of the Internet can increase academic performance and certain other skills (Packard 2007). Despite the benefits however, the Internet can bring about risks, especially for those on the autism spectrum. Some of these risks include the following:

- An increased chance of being bullied
- Inadvertent sharing of personal information such as name, address, phone number, and social security numbers making someone vulnerable to identity theft
- The chance of viewing of inappropriate information or pictures, either violent or pornographic
- On-line sexual activity which can become addictive
- The possibility of unintended contact with militant groups
- The ability to purchase items, both legal and illegal
- The possibility of on-line gambling and possible addiction to virtual casinos due to compulsive behaviors

Historical Background

Studies have consistently shown that people with special needs are at a greater risk of being bullied than their peers (Baumeister et al. 2008). These autistic individuals are set apart as different, and they have characteristics that isolate them from others and make them targets. In one study of children with autism, rates of bullying were over 44% (Montes and Halterman 2007). Children and adolescents with Asperger's syndrome showed increased rates of being a victim of bullying (Carter 2009) with self-reported rates of 75% in one study (Little 2001). Higher rates of verbal and physical attacks are believed to arise from difficulties with social interaction and the failure to read social cues which is a trait of those on the spectrum (American Psychiatric Association 2000). This makes them more likely to be bullied, as they are perceived as odd and different. The frequency of aggressive behaviors in spectrum disorders also increases the chance that they might perpetrate bullying behaviors.

Current Knowledge

Cyber bullying is the result of technology, such as e-mail, instant messaging, cell phone texts, or social network sites being used as a tool for bullying (Kowalski and Limber 2007). There has been little research on cyber bullying and spectrum disorders, but one study that examined the prevalence of cyber bullying via the Internet found that 7% of children aged 12–19 reported being cyber bullied via the Internet and 4% said they had been cyber bullied through text

messaging (Didden et al. 2009). Under 50% of victims of cyber bullying report not knowing the identity of their abuser, which clearly differentiates cyber bullying from traditional bullying as people tend to say and do things anonymously that they would not do in a one-on-one interaction (Kowalski et al. 2008). This can also occur any time of day or night which leaves victims feeling extremely vulnerable. For those on the spectrum, the fear of having technology taken away from them by their parents makes them reluctant to report this bullying to an authority figure. For children with special needs, the Internet might be an easier way of socializing with peers because of their social skills deficits and lack of empathy, yet will likely lead to problems in the virtual world and increased likelihood that they will be involved in cyber bullying. Children who have reported on-line harassment have been found to have less developed social skills (Shea and Wiener 2003). In a study conducted in 2011 by Kowalski and Fedina, over 21% of those surveyed indicated they had been cyber bullied within the past 2 months, while just under 6% said they had perpetrated cyber bullying at least once within the same time period. Parents in this study seemed rather uninformed about their children's experiences with cyber bullying. Seventy-three percent said their child had never been cyber bullied and another 12% reported that they did not know. Twelve percent indicated that they did not know if their child had perpetrated cyber bullying. Eighty-five percent claimed that their child had never cyber bullied anyone, yet only 9% of the parents said that they had ever discussed cyber bullying with their child despite the fact that 51% of the parents acknowledged that they knew something about the topic. The most common means of cyber bullying reported was through instant messaging (66.7%) with social networking sites coming in second (60%). A large percentage of those who were cyber bullied indicated that the perpetrator was a friend (50%) and 37.5% indicating the perpetrator was another student at school. Twenty-five percent said they did not know who the perpetrator was. The results of this bullying often lead to anxiety, depression, and low self-esteem.

While being bullied on the Internet is certainly an issue of concern, it is becoming more common to read about sexual predators finding their victims on the net. Teens especially will use their computers late at night, unmonitored by a parent, and are more likely to come across sex abusers looking for victims (Dennis Debbaudt, *Safety Issues for Adolescents with Asperger Syndrome* 2003). While often, parents are pleased that their child has "a friend," the concern for the type of friend is absent and the very literalness of those on the spectrum puts this population in danger.

The FTC stated that identity theft is the number one complaint they get and has continually increased by 20% each year. On the Internet, this can occur by using unsecured websites and divulging information such as social security numbers. It is of utmost importance that individuals with autism understand the importance of using secure websites when engaging in on-line shopping or whenever using a credit card on the Internet. This needs to be explained as making sure that the URL of the website starts with `https://` not `http://`. That extra "s" is what signifies the website as "secure." It is also imperative that autistic individuals understand the types of information that should not be shared on the Internet. It is not uncommon to discover that many people with autism have unknowingly purchased subscriptions to magazines, web sites, and other web services due to their impulsivity and lack of discipline in reading the terms and conditions that often come with agreements.

Due to individuals on the autism spectrum's impulsivity, they are unlikely to think ahead of possible consequences or their behaviors. They also have a tendency to become obsessed with things rather quickly. This is often what occurs when an autistic person, often by accident through a misdirected search using a word such as "toy," a misspelled URL, a misleading web site or e-mail, or a link or photo sent by a peer or through spam, finds pornography on the Internet (Wolak et al. 2007).

While many believe spending time playing video games can be a waste of time, it has been found that these games help children with autism learn to cope with noise, regulate their balance,

and improve sensory processing (www.newswise.com). Vision Audio, Inc., has created EASe (Electronic Auditory Stimulation effect) video games and audio CD's that are therapeutic tools for children on the autism spectrum disorder and those diagnosed with auditory hypersensitivity, central auditory processing disorder, or sensory integration disorder. Therapists have clinically tested the nonviolent EASe video games since 2007 with positive results. The sensory events in the virtual world of these games eventually create a repertoire of experiences that help the autistic child learn to cope with similar events in the real world.

Future Directions

Interventions

Being concrete and establishing rules for social networking sites is particularly helpful for someone on the spectrum. Talking with the individual and explaining clearly what each rule means is extremely important. Rules should be posted near the computer for a constant reminder of appropriate behaviors such as the following:

1. Talk only with friends.
2. Keep address, phone number, social security number, and banking information secret.
3. Talk to a parent or guardian when someone you do not know tries to talk to you.
4. Think before posting comments. Ask yourself if anyone is going to care before you start typing. Will the person at the other end understand if you are joking?
5. Be careful about posting photos. Make sure all photos are appropriate for viewing and also that other people who may be in the photo are okay with their pictures being posted as well.
6. Do not do anything online that you would not do in real life.

There are also Internet safety symbols created by Widget Software that can be downloaded at <http://www.childnet.com/kia/sen/widgetsmart.aspx>. Each symbol is hand-drawn, clear, and concise and illustrates a single concept without

adding unnecessary information. (<http://www.childnet.com>).

It is crucial that the individual with autism understands the consequences of inappropriate behaviors. For a younger person or teen, it might be losing computer privileges with the understanding that correcting these behaviors will reverse this consequence in time. For someone who is an adult, it might be explaining that their behaviors could bring about danger to the family and this may result in their being asked to find another place to live or having their employment terminated if they are an employed adult.

Sometimes being this concrete is what is necessary for the individual with autism to understand that conforming to social norms is necessary.

As a parent or caregiver, there are other precautions that can be taken when the child with an autism spectrum disorder claims to have met a "friend" on-line such as something known as "time checking." This is when the correspondent holds up a newspaper with the date and time (not unlike a hostage displaying a newspaper), takes a picture of him or herself and emails it back immediately. This instant validation process makes it very difficult for an on-line predator to operate anonymously (<http://www.autismkey.com/internet-safety-and-your-child-with-autism/>). Installing software such as NetDog Filter (<http://www.netdogsoft.com>), will block all porn websites in the background when your child is on the Internet and protect them from stumbling into pornography by accident. For young children, there is a Disney game called Surf Swell Island. It teaches basic safety rules and it is free to download at <http://disney.go.com/surfswell/index.html>. The questions are read out loud by the narrator, but the child has to be able to read and choose the answer. The child goes through four areas (Privacy Falls, Virus Cave, Temple of Tact, and Challenge of Doom).

Other options are social networking sites specifically for individuals with autism (<http://www.autismspeaks.org>) such as:

WeAreAutism.org – Share, talk, and communicate in a user-led social network for individuals,

family members, and those members of the community. Share the wealth of your experience and plan for the future with those like you. Find others with similar interests and goals. WrongPlanet.net – Wrong Planet is a web community designed for individuals (and parents/professionals of those) with autism, Asperger's syndrome, ADHD, PDDs, and other neurological differences. They provide a discussion forum, where members communicate with each other; an article section, with exclusive articles and how-to guides; a blogging feature; and a chat room for real-time communication with other Aspies. AutismSpeaks.Ning.org – Autism Speaks Social Networking Site. This online community was created as a support forum for those affected by autism. WeAreAutism.org – Share, talk, and communicate in a user-led social network for individuals, family members and those members of the community. Share the wealth of your experience and plan for the future with those like you. Find others with similar interests and goals. WrongPlanet.net – Wrong Planet is a web community designed for individuals (and parents/professionals of those) with Autism, Asperger's Syndrome, ADHD, PDDs, and other neurological differences. They provide a discussion forum, where members communicate with each other; an article section, with exclusive articles and how-to guides; a blogging feature; and a chat room for real-time communication with other Aspies. AutismSpeaks.Ning.org – Autism Speaks Social Networking Site. This online community was created as a support forum for those affected by autism. Installing anti-virus software is critical for Internet security and safety. Some highly rated software used in removing viruses, malware and spyware include: McAfee, F-Secure, Norton, Kaspersky, and TrendMicro.

Interoception

Kelly Mahler

Mahler Occupational Therapy, Hershey, USA

Definition

The sense of the internal, physiological condition of the body and organs (Craig 2002). Interoceptive signals arise from bodily tissues and organs such as the heart, lungs, GI tract, bladder, and skin. Sensing these interoceptive signals leads to the experience of body states such as pain, hunger, satiety, thirst, elimination, and sexual arousal. Furthermore, awareness of these internal body signals leads to the clear detection of emotions including anxiety, frustration, and calmness. An intact interoceptive system is positively correlated with emotional regulation (e.g., Füstös et al. 2012), intuitive eating (e.g., Herbert and Pollatos 2012), typical pain response (e.g., Weiss et al. 2014), self-awareness (e.g. Modinos et al. 2009; Tsakiris et al. 2007), intuitive decision-making (e.g., Bechara and Damasio 2005; Dunn et al. 2010; Gu and Fitzgerald 2014), and emotional perspective taking (e.g., Grynberg and Pollatos 2015; Singer et al. 2004). Conversely,

interoceptive differences are correlated with challenges such as higher levels of depression and anxiety (Paulus and Stein 2010; Avery et al. 2014).

Interoceptive differences have been found in individuals with autism spectrum disorder (Fiene and Brownlow 2015; Garfinkel et al. 2016). Furthermore, the insula, the area of the brain that processes interoceptive information (Critchley et al. 2004), is commonly affected in individuals with ASD providing a brain-based explanation for the interoceptive differences reported by many individuals with ASD (Di Martino et al. 2009, 2014; Uddin et al. 2013; Dickstein et al. 2013; Nomi and Uddin 2015). Given that interoception influences many areas that are often affected in individuals with ASD such as emotional regulation (Laurent and Rubin 2004; Mazefsky et al. 2013, 2014; Samson et al. 2014, 2015), interoception is emerging as an important consideration and area of study within the field of autism.

Interpersonal Skills

Nirit Bauminger-Zviely

School of Education, Bar-Illan University, Ramat-Gan, Israel

Definition

Interpersonal skill is a broad term used to denote all types of human social and emotional interactions with each other. It is encompassing individual’s capabilities to interact efficiently with peers and adults as well as their capabilities to form affective ties or social relationships in the form of attachment with a main caregiver, friendship with peers, and romantic relationships. Social interaction (SI) is defined as a reciprocal process in which children effectively initiate and respond to social stimuli presented

by their peers or adults in diverse social settings and situations. Whereas, social interactions can be sporadic and include various individuals, social relationships inherently denote a mutual process of continuous interactions with a specific exclusive individual over a long period that enables the evolvement of affective bonding, closeness, and intimacy. Interpersonal interactions and skills are the basic unit of which social cognition (the understanding of self and others and the interaction between self and others) derives.

Interpersonal Supports

Barbara A. Cook
Department of Communication Disorders, Center of Excellence on Autism Spectrum Disorders, Southern Connecticut State University, New Haven, CT, USA

Synonyms

Peer supports; Transactional supports

Definition

Interpersonal Supports are activities or strategies provided by peers, teachers, parents, and community members which increase students' overall interpersonal skills for increased social interaction with one or more individuals. The tasks or skills to be targeted include joint attention, perspective taking, social and pretend play, social engagement, and social problem-solving (Luiselli et al. 2008). Interpersonal supports reflect the understanding that fostering social communication is an integral part of an individuals' day and must occur across a variety of social partners. It is an extension of individual or small group support provided by professionals for generalization. A key component of interpersonal supports is a shifting of emphasis away from the student to an emphasis on training and educating members of the students' interactive day to effectively facilitate appropriate social interaction (Marans et al. in Volkmar et al. 2005).

Students with ASD have a natural interest in their age level peers; therefore, these peers become an important interpersonal support to the student with ASD. Peers who have received training to adjust their communication style and interaction with the student with ASD are effective at facilitating and increasing appropriate interactions. Research supports the use of peer-mediated interventions, including peer mentors in naturalistic settings. Examples which have been published include Peer Integrated Play Groups by Pamela Wolfberg (2003); Peer Buddy Skills Training by K. English et al. (1997); and Peer implemented Pivotal Response Training by K. Pierce and Schreibman (1995, 1997) as cited in Volkmar et al. (2005). Additional resources for implementation of peer mentor programs may be found on the National Mentoring Resource Center website (<https://www.nationalmentoringresourcecenter.org/index.php/what-works-in-mentoring/resources-for-mentoring-programs.html?id=237>).

Although teachers and parents may have extended knowledge and understanding of social communicative competency levels in students with ASD, they will benefit from additional training and support regarding their own

communicative style and its impact on fostering increased social communication in the student with ASD. Teachers and parents, through their daily interaction with students with ASD, will provide valuable interpersonal support for the development of social communicative competency (Marans et al. in Volkmar 2005). An example program that has been designed to provide in depth training to parents and teachers is the Program for the Education and Enrichment of Relational Skills (PEERS) for Adolescents, for Adults, and for Preschoolers by Elizabeth Laugeson (2010). This program utilizes didactic instruction to guide parents toward understanding techniques that support conversational management skills.

Students with ASD will want to participate in community-based activities which reflect their personal interests and preferences. In the outset of participation within these activities, it will be necessary for parents to provide primary support that allows their child to successfully engage in the community. However, it will be necessary to consider means of providing training to those members of the community that will likely engage in interpersonal interaction with the individual with ASD. This training will need to include support strategies to foster and increase student social communicative competency within these community settings (Marans et al. in Volkmar 2005), such as core conversational management skills (eye contact, asking questions, commenting, and body proximity). Additionally, provisions under IDEA (2004) require that all educators within the Pre-K to 12 school setting receive this type of training. While there is not a current policy requiring training at the college/university level, as a growing number of individuals with ASD attend college, it will be imperative to develop training for those who provide interpersonal support to students on campus that includes best methods to encourage use of expected skills of conversational management and social interaction.

Interpersonal supports are beneficial to increasing the social communicative competency of students with ASD by utilizing all of the members of their interpersonal circle to facilitate and

foster positive social interaction that is engaging and reinforcing, and within multiple environments. As a result, individuals with ASD who receive this support, will have a broader peer network that will lead to an increased social capital, thus having a larger impact on successful outcomes.

Interventions for Increasing Acceptance of New Foods

Liam R. Chawner
University of Leeds, Leeds, UK

Definition

Interventions aimed at increasing acceptance of new foods into the diet involve using a range of techniques based on exposure to foods, conditioning, and family training or environmental changes. Acceptance is a broad term that includes any behavior from willingness to try a new food (e.g., tasting, putting food in the mouth) to increasing the number of whole foods eaten by the individual. It is often a goal of these interventions to increase intake of foods from different food groups in order to ensure a variety in the diet. New foods can be identified as foods that are not usually eaten as part of the habitual diet. These food items, however, do not have to be novel because familiar foods, or foods that were previously accepted, can also often be refused.

Historical Background

Autism as first described by Leo Kanner (1943) noted that feeding problems occur in many cases. These problems included food refusal, limited food repertoire, challenging behaviors around eating, and a variety of unusual eating behaviors that were individual to each case. Since then, feeding problems have been estimated to be prevalent in up to 89% of children with autism (Ledford and Gast 2006), encompassing a vast range of atypical eating behaviors. Although feeding problems occur more frequently in children with autism than in typically developing peers, issues with eating are not necessary or sufficient for an autism diagnosis. It has therefore been proposed that factors associated with autism, such as insistence on sameness, social communication deficits at mealtimes, or sensory sensitivities, may either cause or affect the likelihood of food refusal and food selectivity.

The literature regarding treatment of feeding problems has previously addressed food refusal and challenging behaviors more comprehensively than other eating behaviors such as limited food repertoire (limited dietary variety). This has led to a focus on food refusal only in clinical populations, where the problem has led to high levels of medical or psychological distress to the child or their family that it is deemed to warrant professional intervention (Dovey et al. 2009). This often includes conditions resulting in failure to thrive, growth faltering, or impact on cognitive development, usually as a consequence of nutritional or energy deficiencies. Where necessary, treatment may be medical in nature (e.g., percutaneous endoscopic gastrostomy (PEG) fed) to increase consumption of energy; however, the focus of many interventions to treat food refusal with the aim to increase intake of new foods has had a behavioral focus.

Historically, the goal of increasing acceptance of foods has been addressed using applied behavioral analysis (ABA) techniques such as that of operant conditioning (Riordan et al. 1980), including differential reinforcement of alternative behaviors and escape extinction (including non-removal of the spoon). Forced feeding and

overcorrection procedures have also been used previously to increase food intake and to correct unwanted eating behaviors. However, these punishment-based techniques are less frequently reported in the current literature and are only used clinically when other procedures have not been successful. Further techniques based on exposure, such as stimulus fading and demand fading, have also been developed as forms of systematic desensitization toward new foods. Yet despite these techniques being available, it was suggested in the late 1990s that interventions using positive reinforcement are useful to increase acceptance of foods, while non-removal of the spoon may be useful to correct food refusal (Kerwin 1999). However, due to the heterogeneity of the autism population, this conclusion has generally not been accepted, and the implementation of interventions has become more individualized to the needs of each individual child. Interventions are frequently tailored to specific causes of feeding problems, severity of feeding problems, and preferred outcomes in increasing acceptance of new foods.

In the last 20 years, the problems of food refusal and limited dietary variety have been collated with high-frequency intake of single food items under the broad term selective eating (Bandini et al. 2010). Selective eating acknowledges not only the wide range of eating behaviors that are considered problematic but also feeding problems that occur in most children with autism and not only in clinical populations. Therefore, most children with autism could benefit from healthy eating interventions that introduce new foods. This assumption is a direct response to problems of nutritional deficiencies and overweight being highlighted in children with autism. Consequently, interventions that aim to increase acceptance of a variety of new foods have become a priority. However, although interventions generally succeed in the acquisition of appropriate feeding behaviors, in many cases the maintenance of these feeding behaviors has been much more difficult to achieve.

Rationale or Underlying Theory

Interventions for accepting new foods assume that many foods are already refused in the child's diet due to selective eating. Accepting new foods attempts to address food selectivity by increasing the number of different foods that are eaten, as well as the amount of each new food eaten. It is thought that a variety of attributes in a child with autism could lead to selective eating, including unfamiliarity (food neophobia), sensory sensitivity (or tactile defensiveness), fear or previous food experiences (e.g., choking), sensitivity to food stimuli (color, shape, smell, taste, temperature, etc.), biological food intolerance, repetitive behaviors, gastrointestinal problems (e.g., constipation, reflux), and food allergy (Sharp and Postorino 2017). While this list is not exhaustive, it aims to highlight the heterogeneity of the population, which is reflected in the range of interventions available to attempt to treat food selectivity, based on individual needs.

In addition to child-specific traits, parental anxiety and unintentional reinforcement of non-preferred behaviors have also been suggested to maintain selective eating behaviors in the child. This may include preparing special meals for the child that differ from that of the rest of the family or removing the child from the eating situation if they display challenging behaviors (e.g., tantrums, throwing food, holding food in the mouth, etc.). Regardless of the underlying cause of selective eating, all interventions to increase acceptance of new foods consider the problem as a behavior that can be altered.

Goals and Objectives

Treating food selectivity aims to address the effects of selective eating more often than its causes. The effects that are targeted include increasing variety in the limited diet, reducing the amount of foods that are refused, and increasing the volume of non-preferred foods that are consumed. Studies often have secondary goals to

reduce any challenging behaviors during feeding occasions. Likewise, changing parental feeding behaviors may also be an appropriate goal in order to provide structure to mealtimes, although this is usually measured in relation to the child's eating behavior, rather than the parent's feeding behaviors.

The causes of food selectivity can also be addressed, but this is not usually explicitly reported in the literature. For example, sensory sensitivities may be decreased through multiple exposures to target foods, and therefore desensitization to the food stimulus occurs. These goals are not only relevant to psychological practice when a child presents with a feeding problem, but also for parents that have difficulty encouraging their child to eat certain foods and in educational settings where children's consumption of foods may also be limited.

Treatment Participants

All children, whether typically developing or diagnosed with autism, can benefit from an intervention that promotes eating a wider variety of foods and therefore, a healthier and more balanced diet. However in autism, the type of intervention delivered will depend on the individual case and their hypothesized cause of selectivity, what specific behaviors will be a target for change, and the severity of their selectivity. Although very little research has been conducted specifically to compare severities of selective eating, it is thought that severity will affect many aspects of treatment and its outcomes. Due to a more restricted diet, severely selective eaters might first need to increase their intake of a select few target foods before trying new foods and increasing variety, whereas it could be more appropriate for mildly selective eaters to increase acceptance for a variety of new foods, since these children already eat a wider variety of foods than severely selective eaters.

In addition to severity, age is a particular concern for when to intervene. Current research

would suggest an early intervention for a better prognosis (e.g., 2–8 years old), as food selectivity in autism is a stable trait that continues into adolescence (Bandini et al. 2017). Therefore, early intervention that promotes acceptance of a range of new foods is preferred as this behavior will be more likely to continue into adolescence if it is established first in childhood. Although it is suggested that eating behaviors are more difficult to change as the child gets older, a few case studies have reported positive changes in young adults after intervention. Additionally, when targeting the eating behavior of children, parental training is often a large part of delivering an intervention because parents will be the people feeding the child after the intervention finishes. Therefore, the parent must be willing and cooperative in order to learn the techniques that are successful at encouraging their child to accept new foods.

Lastly, despite most intervention research being conducted in children with autism, children targeted by feeding interventions to increase acceptance of new foods need not have a diagnosis of autism. Similar positive outcomes have been observed in children with other neurodevelopmental diagnoses including learning disability or developmental delay. If treatments are tailored to the individual's needs, then factors such as diagnosis and additional needs (e.g., communication ability) may be a barrier to an intervention having success, but will not necessarily make the individual unlikely to benefit from intervention.

Treatment Procedures

For increasing acceptance of new foods, three main categories of intervention have been identified based on exposure to food, conditioning techniques, and methods including family training or environmental changes (Chawner et al. 2019). Each of these groups of intervention has an array of techniques that can be used to increase acceptance of new foods (Table 1). The unique qualities of each category of intervention are determined by its explanation for the eating problem behavior.

Lack of experience or physical sensitivity to food can be addressed by exposure techniques; however, a more complex relationship with the food may need to be addressed with reinforcers and punishments (e.g., removal of a reward) as motivation to eat the food. Lastly, eating problems may stem from, or be maintained by, the environment. Therefore, changing aspects of the environment or training parents to change how feeding occurs can be useful. Most often, successful interventions will utilize a combination of these techniques.

Most research using these techniques implement them in controlled clinical settings. Less studies have implemented interventions in the home and even fewer have attempted school settings. However, as the setting changes, so does the role of the treatment provider. In the clinic, the treatment provider as the therapist has a role to assess the problem, plan an intervention, and change this plan if it does not work, whereas in the home setting, the professional will often train parents to carry out procedures in the hope that parental practices can continue to have positive effects after the intervention finishes. Ideally, all interventions designed to increase acceptance of foods in children should have parental involvement (Ledford et al. 2018). In this case, the treatment provider has a duty to ensure that parents are implementing the procedures correctly and safely, while not inadvertently causing any unwanted behaviors or outcomes.

Additionally, most interventions have been carried out only with individual children on a one-to-one basis. There is very little evidence for implementing interventions in groups due to the individuality of needs and the specific problem that is being addressed, as this will be different for different children. However, some research has reported delivering exposure interventions and environmental changes in schools or cafeterias to groups of children. These interventions make appropriate use of nonclinical settings, so severity of food selectivity is likely to be milder and exposure to new foods may produce preferred changes in behavior. It is also unlikely that exposure techniques alone will have adverse effects on children's eating behavior, unlike the potential adverse effects associated with using more

intensive interventions incorrectly (e.g., escape extinction). Therefore, these types of intervention are more appropriate for nonclinicians to implement safely to groups of children.

Furthermore, duration and frequency of the interventions are also very varied. Frequency can differ between one or two times per week or be as intense as three times per day. Duration has also been reported from 2 sessions to over 200 sessions, with some interventions lasting anywhere from a few days to over 6 months. Each session length is also variable. Although there appears to be no standard for time, this massive range of durations and frequency of session can be explained by the variety of different interventions used, severity and causes of selective eating, behaviors that are targeted to be changed, and clinician time. It is often not reported whether the intervention stops because the target outcome has been achieved. Therefore, there is no guarantee that a shorter, more intense intervention will have preferred effects, nor a longer and slightly less intense intervention. Consequently, interventions are tailored to the individual rather than following a specific standard course of intervention to increase acceptance of new foods.

Efficacy Information

Overall, all interventions and techniques mentioned in Table 1 have been shown to have some positive effects on increasing acceptance of new foods in children with autism (although some techniques changing aspects of the environment alone, e.g., special plates, have not been supported). However, because most interventions have been reported as effective in case studies, there is no one intervention that can be determined as better or worse than the other interventions. For this reason, it has been suggested that there is a hierarchy of interventions and techniques to use in increasingly challenging cases. If food selectivity is mild, environmental changes, systematic desensitization techniques, and family psychoeducation may be a valid form of intervention, while if the food selectivity is more resistant to change, conditioning techniques may be used to increase

Interventions for Increasing Acceptance of New Foods, Table 1 A description of intervention techniques used to increase the acceptance of new foods

Method/intervention	Description
Based on conditioning	
Differential reinforcement of alternative behavior (DRA)	Positive reinforcement of “target” or “good” behaviors (e.g., reinforced with food, toys, stickers, and verbal praise) on a variable schedule
Non-contingent reinforcement (NCR)	Reinforcement that is not dependent on completing a “target” behavior (e.g., swallowing a non-preferred food item)
Lag schedules	A schedule of reinforcement in which a single response, or a sequence of responses, is reinforced only if it varies from previous responses or sequences of responses
Escape extinction (EE)	This technique describes various procedures that prevent escape from the feeding situation (including non-removal of the spoon: NRS and physical guidance)
Non-removal of the spoon (NRS)	A type of EE that holds a spoon close to the mouth until the food is accepted
Physical guidance	Guiding the mouth open or applying small pressure to the jaw to assist with accepting food into the mouth
Based on exposure	
Systematic desensitization	A method designed to reduce avoidance behavior toward an adverse stimulus by gradually increasing exposure to it
Stimulus/texture, portion and demand fading	Three methods of systematic desensitization
	Stimulus/texture fading: Gradually changing the texture of a food (e.g., runny mashed potato can be made increasingly thicker)
	Portion fading: Gradually increasing the portion size of a new food (e.g., from the size of a pea to a recommended serving)
	Demand fading: Gradually increasing behaviors that are required by the participant (e.g., increasing the demand from one bite to three bites)
Simultaneous presentation	A type of flavor-flavor conditioning that pairs a non-preferred food with a preferred food or liked condiment
Using new foods similar to those previously accepted	Using similar foods to those already accepted (e.g., matching by food group, brand, color, texture, etc.)
Modeling	Watching others eat the non-preferred food (e.g., parents, siblings, friends)
High-probability sequences	This requires asking the participant to complete a high-probability task (e.g., put spoonful of preferred food in the mouth) before asking them to perform a low-probability task (e.g., put a spoonful of non-preferred food in the mouth)
Choice of foods	Allowing the participant a choice between different non-preferred foods
Access to preferred food	Allowing or denying access to preferred foods before the non-preferred food is presented
Family and environmental methods	
Psychoeducation	Psychoeducation involves providing education and information to family members about selective eating
Parental training	Most of the techniques described are implemented by clinicians or researchers. Parental training is designed so that parents can implement some strategies themselves
Mealtime plans	Mealtime plans are implemented by the family and focus on areas such as communication, food offered, and the social and physical environment during mealtimes
Positive behavioral support (PBS)	A multicomponent intervention that aims to support an individual. This includes a functional assessment of possible relationships between environment and behavior, which can inform support for eating using appropriate methods (methods in this table) for the individual
Environmental interventions	Environmental interventions change an aspect of the physical setting. This can include changing the layout and placement of healthy foods in lunchrooms, using special plates that show how much of the plate should be filled with portions from each food type and using games to encourage fruit and vegetable intake

motivation to accept new foods by using reinforcers to shape behavior. Further up the hierarchy, extinction procedures may be used if foods are still not accepted, followed by physical guidance as a last resort in cases where food selectivity poses a threat to health or well-being.

As specific intervention techniques cannot be directly compared adequately, efficacy for the characteristics of interventions is compared instead. One component is whether a single intervention is delivered or whether multiple intervention techniques are delivered together. Systematic reviews have highlighted that using multiple techniques usually results in more preferred outcomes. This may be due to the heterogeneity of selective eating, and using multiple techniques could address several areas of the eating problem that allows for better outcomes. However, because of the case study nature of the literature, it is not the individual techniques that are supported for their efficacy, but rather the intervention package that is tailored to the individual that has been shown to be effective to increase acceptance of new foods.

Generally, research has found that selective eating interventions appear to be successful at increasing the volume of target foods consumed, but not necessarily to increase variety in the diet (Marshall et al. 2015). It is suggested that familiar foods may be more easily processed from an oral motor or sensory perspective. Therefore, when target foods are used, there is often a lack of generalization to other foods. This is beneficial when reducing refusal of foods, but less so when the aim is to increase dietary variety. The aims of treatment frequently take a stepped approach which increases the time needed for behavior change to occur. First, the aim is to overcome any food refusal, then to reduce any challenging behaviors, and finally to establish a nutritionally adequate diet, which would include a variety of foods. It is possible this last step is not achieved or reported in most case studies because it is an ongoing process. Due to the length of time needed in some cases to increase dietary variety, the duration of intervention may not be long enough to achieve this goal because of clinician time and

priorities. Therefore, if parents are not taught the therapist's intervention techniques, then any changes to eating could stop when the intervention does. Any further benefit gained from the parent's implementation of techniques after intervention would also not be recorded.

Similarly, persistence of effects is not well understood from the literature. This is because many reports do not include follow-up time points after intervention. However, of those that do, there is often some loss of performance, yet outcomes are generally reported as better than before the intervention. Most studies also do not include generalization measures for new foods, a new location, or a different implementer of intervention, although such information would be very useful in order to evaluate the efficacy of individual interventions. Lastly, while we are aware of factors that predict food selectivity, there is no direct research into which individual differences affect gaining benefit from interventions or for whom interventions work. There are rare reports of other comorbid feeding-related medical problems in each case, and family characteristics or demographics are often not reported to an accurate degree. It has been suggested that higher food selectivity, more feeding-related problems, challenging behaviors, maintenance behaviors from parents, low SES, and lower availability of foods may all increase the difficulty of an intervention being successful. However, these claims are mostly anecdotal and cannot be supported by evidence.

Outcome Measurement

There are many outcome measurements that can be used to determine the success of an intervention for increasing acceptance of foods. These are percentage bite acceptance, number of foods eaten, number of bites eaten (a bite can be defined as a small portion of food that will easily fit in the mouth, e.g., 1.5 cm³), behavioral demands (e.g., accomplishing predetermined behaviors such as putting the food to the lips or inside the mouth),

weighted food intake (grams), and self-report (parental report of what the child has eaten; this could be a food frequency questionnaire of all foods eaten in the last year or a 3-day food diary). Other outcome measures may include the reduction in challenging behaviors, such as throwing food. This can be measured by coding the frequency of such behaviors during each session.

The main difference between outcome measurements is whether it is a macro measurement (e.g., number of whole foods) or a micro measurement (e.g., percentage of bites accepted). This will be based on what is achievable for the child in the available timeframe, what is an acceptable goal to achieve, and what the intervention is designed to target. Choosing an outcome measure, like choosing an intervention, also depends on the severity of each case. In more severe selective eating cases, an attempt to try the new food may be an appropriate goal. It could be deemed a successful intervention if the child puts the food in their mouth even if they do not swallow it. In these cases, it may take a long duration to increase intake and therefore smaller goals must be set initially. However, number of whole new foods eaten may be an achievable goal if the child is mildly selective and already eats foods from different food groups. Although it is acceptable to choose an outcome measure based on what is achievable, much research does not report why the outcome measure they have used was chosen initially.

Qualifications of Treatment Providers

The qualifications needed to provide intervention depends on many factors including the severity of food selectivity, the type of intervention being delivered, and the initial problem that the intervention was designed to address. This is because if a child is very selective and the intervention is not conducted well, it may result in further selectivity or feeding problems for the child. Therefore, conditioning techniques should be implemented by trained professionals or researchers that have

experience delivering behavioral, or applied behavioral analysis (ABA), techniques. Although some studies have trained parents to be able to implement these procedures, these parents are trained by professionals with an ABA qualification. Alternatively, systematic desensitization and environmental change techniques could be implemented by parents or teachers to increase exposure to new foods with low risk of adverse effects. Nonetheless, they should still be trained in the specific intervention by an appropriate person and supported throughout its delivery.

Interventions to Support Transition to Adulthood for Individuals with Autism Spectrum Disorder

Laura G. Klinger¹ and Katerina M. Dudley²

¹TEACCH Autism Program, Department of Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

²Department of Psychology and Neuroscience, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Definition

The transition from adolescence to adulthood (i.e., ages 18–25) is a critical developmental period often marked with multiple stressors as individuals become more independent and explore new roles (e.g., living independently, employment, and postsecondary education). For individuals with autism spectrum disorder (ASD), this period is particularly difficult, with most exiting high school and leaving behind the integrated child services and supports they once knew. There is an urgent need to study outcomes and effective

transition to adulthood interventions to help support individuals with ASD and their families during this time.

Historical Background

Current prevalence estimates from the Centers for Disease Control and Prevention (CDC) indicate a 178% increase in school-age children diagnosed with ASD from 1 in 150 8-year-olds in 2002 to 1 in 54 8-year-olds in 2016 (Maenner et al. 2020). Of note, the first cohort of children in these CDC studies is now 26 years old, suggesting that we can anticipate a parallel increase in adolescence and young adults with ASD transitioning into adulthood. Research has indicated that quality of life (QOL) outcomes for adults with ASD are poor and characterized by low rates of employment, a plateau or decline in independent self-care skills, a lack of access to services, and high rates of anxiety and depression (e.g., Anderson and Butt 2017; Dudley et al. 2019; Hillier et al. 2018; Roux et al. 2013). For instance, in a nationally representative sample of 21–25-year-old young adults with ASD ($N = 620$), only 53% had ever received paid work since leaving high school, and only 33% had a current job (Roux et al. 2013). In addition, 50% of adolescents and young adults with ASD experience a disruption in vocation (e.g., job loss) or postsecondary education (e.g., expulsion) within the first 3 years post-high school (Taylor and DaWalt 2017).

At least 42% of individuals with ASD have average or above-average cognitive ability and the potential for competitive employment (Maenner et al. 2020). One might assume that those with ASD and higher IQs would have more positive outcomes; however, data do not support this assumption. Data from the Adult Consumer Survey, a national representative sample of adults with ASD using developmental disability services, showed that only 23% of adults with ASD without a co-occurring intellectual disability had a paid job in the community (Roux et al. 2017). Taylor and Seltzer (2010) found that

young adults with high functioning ASD (i.e., those with average to above-average IQs) were three times more likely to have no daytime activities after high school than those with ASD and comorbid intellectual disability (ID). They also found that only 18% of those with high-functioning ASD received employment services after leaving school compared to 86% of those with comorbid ID. For those that are employed, adults with high-functioning ASD are frequently underemployed, switch jobs often, have difficulty adjusting to new job settings, and make less money than their neurotypical peers (Hendricks 2010). High unemployment rates contribute to the \$1.4 million estimated lifetime cost of supporting an adult with ASD without co-occurring intellectual disability (Buescher et al. 2014). These results suggest that individuals with ASD without comorbid ID may be “falling through the cracks” during the transition to adulthood and are in need of additional services.

Not only are employment outcomes poor for this population, but similar challenges exist related to postsecondary education during the transition to adulthood. While a growing number of individuals with ASD are seeking higher education opportunities (Gobbo and Shmulsky 2014), only a fraction completes a degree (Shattuck et al. 2012). Newman et al. (2011) reported that 39% of students with ASD who started postsecondary completed their program. This contrasts with a graduation rate of nearly 60% for neurotypical students who start postsecondary education. Notably, when young adults with ASD do attend college, the vast majority of them attend 2-year or community colleges for at least part of their college experience. Roux et al. (2015) reported that in a nationally representative sample of those who attended postsecondary education, 88% of young adults with ASD attended 2-year colleges or vocational/technical schools. Because most of those who pursue post-secondary education will go through the community college system, community colleges could be an ideal location to provide transition interventions for young adults with ASD.

To attempt to address the growing needs of adolescents and young adults with ASD, there has been a substantial increase in requests for transition to adulthood services; applications for Vocational Rehabilitation (VR) services to support transition-aged individuals with ASD increased by 571% between 2003 and 2012 (Alverson and Yamamoto 2017). However, simply increasing access to services does not seem to be enough to improve outcomes (Alverson and Yamamoto 2017; Burgess and Cimeria 2014). In a review of over 35,000 transition-aged adults receiving VR services, only one-third of adults with ASD achieved successful employment (Burgess and Cimeria 2014). Thus, traditional VR services and supports appear to be inadequate in fully supporting the needs of individuals with ASD transitioning to adulthood. Thus, there is an urgent need for the development of effective, evidence-based transition to adulthood interventions that target ASD-specific challenges, promote better QOL, and improve employment and post-secondary outcomes.

ASD-Specific Challenges

While the empirical intervention literature is sparse, there is a growing consensus among researchers, adults with ASD, and caregivers that targeted interventions addressing ASD-specific challenges during the transition to adulthood are desperately needed to help adolescents/young adults develop to their full potential. Across studies using stakeholder (e.g., caregivers, adults with ASD, university professionals) focus groups, interviews, and surveys, several distinct challenges for college-bound and college-enrolled students with ASD have emerged including: executive function skills (i.e., time management, organization) (Wallace et al. 2016), adult-appropriate social skills (i.e., adult relationships, employment setting social behavior) (Hendricks 2010; Hillier et al. 2018), and emotional regulation (i.e., anxiety, coping) (Anderson and Butt 2017; Hillier et al. 2018). While there is little to no information regarding the effective targeting of these domains for young adults with ASD, the

childhood and younger adolescent intervention literature identifies evidence-based strategies to target these skills for those with average to above-average IQs. Overall, the following have been found to be evidence-based strategies to target these domains: *executive function* – visual supports (e.g., visual schedules), explicit rules, and routine strategies; *social skills* – scripts, social stories, modeling, self-monitoring, and role play activities; and *emotion regulation* – coping strategies (e.g., relaxation paired with problem solving) and other cognitive-behavioral therapy strategies (see Klinger and Dudley 2019, for a review).

Transition Interventions

Despite poor employment and postsecondary outcomes experienced by many adults with ASD, there are no published large-scale randomized clinical trials examining the effectiveness of transition intervention programs evaluating either short-term (e.g., changes in executive function) or long-term (e.g., employment) outcomes for young adults with ASD. However, there have been four published pilot intervention studies focused on supporting the transition to adulthood for adolescents and young adults with ASD: (1) *Transitioning Together*; (2) *Acquiring Career, Coping, Executive Control, Social Skills* (ACCESS); (3) *Connections*; and (4) *Stepped Transition in Education Program for Students with ASD* (STEPS).

To provide an initial evaluation of a multi-family group program for high school students with ASD and their parents (i.e., *Transitioning Together*), DaWalt and colleagues (2018) conducted a preliminary waitlist control randomized clinical trial (RCT) to examine the impact on the transition from high school to college (DaWalt et al. 2018). They found the intervention produced increased parent well-being and improved adolescent social interactions. Similarly, a pilot RCT found that the ACCESS program, which was designed for young adults with ASD to improve skills necessary for adulthood, significantly improved adaptive skills, self-determination, and increased coping self-efficacy (Oswald et al. 2018). Hillier et al. (2018) conducted one

noncontrolled (open trial) study examining the effectiveness of an intervention for college students with ASD (i.e., *Connections* program) (Hillier et al. 2018). They reported that participation in a college support group for young adults with ASD was associated with decreased anxiety and loneliness. Lastly, White and colleagues conducted a randomized control study examining the efficacy of the *STEPS* program with 59 16–25-year-old adolescents and emerging adults (White et al. 2019). Significant gains were found in parent-reported transition readiness skills for the treatment group but not the control group. Further, students enrolled in postsecondary education enrolled in the treatment group reported increased adaptation to college compared to the control group. Across these four interventions, findings provide preliminary evidence suggesting that transition intervention programs may be effective at increasing social communication and emotion regulation abilities in individuals with ASD. However, additional intervention development and clinical trials are needed to create an evidence base for transition to adulthood services that specifically target the challenges experienced by adolescents and young adults with ASD.

Current Knowledge

The TEACCH School Transition to Employment and Postsecondary Education Program (T-STEP Program) was created to address the current paucity of interventions targeting executive function, professional social skills, and emotion regulation for individuals with ASD transitioning to adulthood. The T-STEP was originally developed for diploma-track high school students and has moved to implementation in community college settings for students with ASD with average to above average IQs. The decision to transition to a community college setting was based on Roux et al.'s (2015) findings that the majority of students with ASD choosing postsecondary education start this education in community college settings. Further, our local North Carolina Community College System requested assistance supporting the needs of college students with

ASD as their largest community college reported an increase from 6 students with ASD to 126 students with ASD requesting disability services between 2003 and 2014. Thus, community colleges represent an ideal opportunity to provide targeted transition to adulthood services for individuals with ASD.

The T-STEP is a comprehensive, manualized, 12-week transition program that is currently being delivered in community college settings across North Carolina. The program is offered as a Workforce Innovation and Opportunity Act Pre-Employment Transition Service (Pre-ETS) program through a collaboration with the North Carolina Community College System and the North Carolina Division of Vocational Rehabilitation Services. The program is offered as a noncredit earning continuing education course open to 16–21-year-old high school or college students who have completed or are in the process of completing a general education high school diploma. The curriculum includes 36 h of group-based instruction delivered within a traditional academic school semester (i.e., 24 90-min classes across 12 weeks). Students also participate in a weekly campus-based internship to practice the skills learned in the intervention group (2 h/week for 10 weeks). In addition, students participate in 12 h of individual counseling services that are consistent with counseling services currently available on college campuses (i.e., higher education counseling, career counseling, and self-advocacy counseling about how to access disability accommodations at college and at work).

T-STEP Class. A student workbook was created through an iterative revision process with the input of a community advisory board consisting of parents of adults with ASD, self-advocates including a current college student with ASD, educators (high school special education teacher, community college instructor), disability support specialists (community college accessibility services, state disability service agencies), and employment services specialists. Additionally, focus groups were conducted with students completing the program.

Each T-STEP class session includes a review of previously learned concepts, introduction and

practice with new concepts, and a wrap-up in which home practice is assigned. The intervention contains six modules, each targeting pivotal employment and postsecondary education skills that address the specific challenges faced by young adults with ASD. Two modules target executive function skills (i.e., planning/organization; time management/flexibility), two modules target social communication skills (i.e., asking for help, engaging in professional social behavior), and two modules target emotion regulation skills (i.e., accepting corrective feedback, effectively coping with distress). Each module includes skill instruction in a group format, video modeling, and role-play opportunities in large group, small group, and individualized instruction activities. Each module is an integration of evidence-based practices as defined by the National Professional Development Center (Wong et al. 2015) including visual supports, video modeling, schedules, modeling, social narratives, self-management, cognitive behavioral intervention, and reinforcement. Students are taught routine strategies that they can implement across multiple settings. For example, an asking for help routine strategy highlights the importance of identifying “who” to ask for help, “when” to ask for help, “where to seek help,” and “what” to say. To support learning and generalization, these strategies are practiced through video modeling, small group activities, and through campus-based internships.

Work-Based Learning Experiences/Internship.

In addition to the group-based instruction, each student participates in a work-based learning experience or internship that provides opportunities for “real-world” practice beyond the classroom. Internship sites occur on community college campuses and include a variety of settings (e.g., library, academic departments, cafeteria, and science labs) that are matched to each student’s individual interests and goals. Students complete an internship agreement with each internship supervisor and bring an internship notebook that identifies T-STEP skills that should be practiced during the internship (e.g., the internship supervisor supports a student to learn an appropriate social greeting expected at the library; the internship supervisor prompts the student to

use a coping routine when corrected by the supervisor). T-STEP instructors consult with internship supervisors and students weekly to monitor progress and support the implementation of T-STEP skills. Students are expected to participate in at least 20 h of internship activities across the T-STEP program (i.e., 2 h/week).

Individual Counseling. College students enrolled in the T-STEP program also receive 12 1-h weekly counseling sessions that parallel services typically available on a college campus (i.e., job exploration/career counseling, postsecondary education counseling, and self-advocacy counseling). Students receive a workbook that provides instruction in each of these skills. Specifically, students complete career interest assessments and collaborate with career counselors in completing an individualized plan for each student that is appropriate given their abilities. Students also receive counseling to explore college course offerings and postsecondary opportunities related to chosen career pathways and are given resources for success in postsecondary education settings. Finally, students receive self-advocacy counseling focused on accessing disability services and supports at college and at work.

Initial Efficacy. Across pilot research in both high school and community college settings, initial research supports the efficacy of the T-STEP. In an open trial pilot study, 57 students (aged 17–21 years; average age 19.3 years) completed the T-STEP across three community colleges. Students were assessed at baseline and following completion of the intervention. Positive impacts were reported by students, caregivers, and via observational assessments. Specifically, caregivers reported that their students showed significant increases in employment readiness skills (Becker Work Adjustment Profile) including increases in work habits, interpersonal effectiveness, and work performance skills. Caregivers also reported significant increases in everyday self-care skills (Waisman Activities of Daily Living). Students reported significant increases in their ability and opportunity to make choices in their lives (AIR Self Determination Scale). They also reported decreases in symptoms of depression (Center for Epidemiological Studies –

Depression). Further, we created an observational measure (TEACCH Transition Readiness and Employability Evaluation, TREE) to assess the specific executive function (i.e., planning/organization, time management), social communication skills (i.e., asking for help, engaging in professional social behavior), and emotion regulation skills (i.e., accepting corrective feedback, effectively coping with distress) targeted by the T-STEP. Students completed two tasks typical of an office setting (e.g., data entry, filing) with a series of structured presses to assess T-STEP skills (e.g., missing materials were a press for the student to ask for help). On the TREE, significant improvements were seen in executive function, social communication, and emotion regulation skills.

In focus groups, students reported that the program helped prepare them to learn how to function in the adult world so that they could be successful as a college student and in the workplace. They responded that the program was “definitely” worth the time and that they would recommend it to others. Thus, across qualitative and quantitative assessments, initial results are promising for the T-STEP as an intervention addressing ASD-specific challenges during the transition to adulthood.

Future Directions

There is an emerging intervention literature describing transition interventions designed to promote critical skills needed in adulthood (e.g., executive function, social skills, and emotion regulation). Initial evidence is promising, indicating that we can improve the transition to adulthood for adolescents and young adults with ASD through targeted interventions. However, larger randomized control trials are necessary to evaluate the efficacy of these newly developed interventions and to identify individual characteristics (e.g., cognitive ability, language skills, and comorbid anxiety) associated with both positive and negative intervention outcomes. With regard to our research on the efficacy of the T-STEP, two randomized clinical trials are ongoing.

Across transition interventions, future research should not only include measures of short-term outcomes, but also measure long-term changes (e.g., employment, completion of post-secondary degrees, QOL). It is also critical that we move to evaluating the effectiveness of these programs in large-scale comparative efficacy studies (i.e., compare interventions to other evidence-based programs, rather than services-as-usual) and aim to conduct full community-based participatory research in which key community members (e.g., young adults with ASD, parents of young adults with ASD, service providers) are actively involved in research design and implementation. Lastly, dissemination research is needed to implement transition interventions in locations that are accessible to individuals from diverse backgrounds (e.g., in community colleges, community clinics) and that can be implemented by community service providers. The long-term goal is to increase the likelihood for community use and the ability to more effectively support individuals with ASD as they transition to adulthood.

Child-focused approaches

Definition

Child-centered approaches refer to autism interventions that incorporate the child's individual needs, interests, preferences, and choices into the planning and implementation of treatment. Additionally, these approaches are tailored to the child's developmental level and individual strengths.

Historically, treatment plans for children with autism were exclusively adult-directed, with the clinician deciding on the treatment goals, intervention strategies, materials used, and specific activities. Emphasis was placed on using repetitive, drill-like instructional activities as the primary means of teaching the child new skills. This mass trial approach resulted in systematic behavior gains, but the rate of skill acquisition was relatively slow, and children were not highly motivated to learn.

The original call for child-centered approaches was borne out of the establishment of social validity as a central concept in treatment planning, or the consideration of the long-term social value and acceptability of the treatment approach by the child and other key stakeholders invested in the child's outcome (Wolf 1978). By incorporating child-centered components into the intervention approach, the child's motivation to be an active participant in the intervention process is significantly increased, leading to improved task engagement and an increase in the rate of skill acquisition (e.g., Koegel et al. 1987). Examples of

empirically supported child-centered approaches include Pivotal Response Treatment (Koegel and Koegel 2006), Incidental Teaching (McGee et al. 1999), and the SCERTS model (Prizant et al. 2006).

Interview-Informed Synthesized Contingency Analysis (IISCA)

Adithyan Rajaraman¹ and Gregory P. Hanley²

¹UMBC, Baltimore, MD, USA

²Western New England University, Springfield, MA, USA

Definition

The interview-informed synthesized contingency analysis (IISCA; Hanley et al. 2014) is a type of functional analysis (FA) that alternates a single

test and a single control condition, both comprehensively informed by an open-ended interview with relevant caregivers. In general, FAs rely on direct observation of problem behavior (PB) under various conditions in which environmental events are systematically manipulated to detect their influence on PB. FAs are commonly applied in research prior to treating PBs primarily associated with autism and intellectual disabilities (e.g., self-injurious behavior [SIB], aggression, property destruction, disruptive behavior; Beavers et al. 2013; Hanley et al. 2003). FAs have been shown to positively moderate the effects of behavioral interventions (Campbell 2003). In an IISCA, all of the co-occurring environmental events reported by caregivers to evoke and maintain PB are synthesized into a single reinforcement contingency. Whether this interview-informed, synthesized contingency influences PB is determined by rapidly alternating between test and control sessions in which the synthesized contingency is present or absent, respectively. The IISCA is a highly efficient, safe, and efficacious approach to understanding the context in which PB occurs and its likely reinforcement prior to its treatment (Hanley et al. 2014; Jessel et al. 2016; Santiago et al. 2016; Slaton et al. 2017).

One of the features of the IISCA that distinguishes it from other FAs of PB is the use of an individualized, single test condition that relies on a synthesized reinforcement contingency rather than multiple test conditions that attempt to isolate the influence of common reinforcement contingencies. For instance, rather than assessing whether PB is sensitive to attention, escape, or tangible reinforcement by evaluating each of these common reinforcement contingencies in distinct test conditions (e.g., Iwata et al. 1982/1994), an IISCA would determine if PB is sensitive to all three at the same time, if these events were reported by caregivers to co-occur following PB. IISCAs also attempt to closely emulate the specific manner in which reinforcers are established and delivered in natural contexts. An example of a synthesized contingency analysis that clearly reveals the effort to emulate the contextual features of the reinforcement contingency

is evident in a school-based analysis described by Ghaemmaghami et al. (2015). Based on the teacher's report of how she attempted to manage a 6-year-old boy's attempts to aggress or destroy property while maintaining the safety of her classroom, these authors arranged for the boy's PB to result in escape *from* group instruction *to* the opportunity to play with preferred toys while receiving undivided attention from the group's teacher. In other words, rather than seek to understand the main (isolated) effects of several generic reinforcement contingencies, the ecology under which PB is prevalent is more closely emulated by those conducting IISCAs, thereby allowing for possible and more powerful interactions to be revealed (see Slaton et al. 2017) and then leveraged to develop contextually relevant social skills that, due to their functional similarity, replace PB. In addition, rather than arrange putative reinforcement for only dangerous behavior (Iwata et al. 1982/1994), IISCAs arrange reinforcement for the target dangerous behavior (e.g., SIB) as well as all other forms of PB (i.e., precursor responses, e.g., yelling and foot stomping) that are reported to co-occur with the more dangerous forms of PB (Jessel et al. 2016). By opening the class of behavior topographies that may receive reinforcement in the FA, analyses are safer to conduct, and successful outcomes are more quickly achieved (Warner et al. 2019). Last, only one variable differs between the rapidly alternating test and control conditions of the IISCA: the presence or absence of the synthesized reinforcement contingency. Each distinguishing feature of the IISCA described above has precedent in the FA literature; however, the IISCA uniquely combines all of them in the initial attempt to analyze PB.

Historical Background

Lovaas et al. (1965) published the first FA of PB, in which they showed that rates of SIB exhibited by a child with schizophrenia increased when statements of concern followed instances of SIB, an initial example of control of PB via social-

positive reinforcement. Carr et al. (1976) provided evidence of the influence of social-negative reinforcement when they demonstrated that aggression and SIB could be evoked by the presentation of demands and that the termination of demands could serve as reinforcement. Sailor et al. (1968) demonstrated a functional relation between PB and a *synthesized* reinforcement contingency involving the simultaneous removal of difficult academic tasks and presentation of easier tasks with a child with mental retardation. After carefully describing general categories of reinforcement that have been shown to influence PB such as attention, escape, and direct sensory consequences, Carr (1977) provided a cogent argument that identifying environmental factors influencing SIB and other PB associated with developmental disabilities on a case-by-case basis may be a more fruitful pursuit than only attempting to understand the underlying biology or psychopathology of these same PBs. Following these recommendations, Iwata et al. (1982/1994) introduced a comprehensive model for analyzing SIB, one that is largely responsible for the apparent shift toward reinforcement-based interventions for PB based on its function and away from treatments relying on aversive procedures (Pelios et al. 1999).

The procedures outlined by Iwata et al. (1982/1994) are often referred to as the standard FA primarily because they occasioned hundreds of subsequent demonstrations of PB sensitivity to isolated environmental contingencies (Beavers et al. 2013; Hanley et al. 2003). These replications of single-subject analyses yielded useful baselines for developing an efficacious treatment technology (Kahng et al. 2002) and provided important information regarding *what was possible* with standard analyses (i.e., many different topographies of PB were shown to be influenced by attention, escape, tangibles, or direct sensory consequences across many individuals with intellectual disabilities). Relying on a consecutive-controlled case-series design in order to minimize any potential selection or publication bias favoring particular outcomes, Hagopian et al. (2013) more recently showed *what was probable* with a

standard FA. These authors reported that standard FAs were unable to detect a behavioral function in 53% of applications (94 of 176). Hagopian et al. showed that procedural modifications improved the ability of the analysis to detect behavioral function from 47% to 87%. In a review of published FAs, Schlichenmeyer et al. (2013) also described many of the unique, case-specific, incremental changes to the standard analysis model in the context of initial analysis failure. Noting the prevalence of particular changes to the standard FA that often yielded detection of behavioral function, Hanley (2010, 2012) suggested that these same changes be incorporated into initial analyses; the most important change being the incorporation of qualitatively unique reinforcement contingencies designed from interviews and observation into the initial FA. Hanley et al. (2014) then provided an empirical demonstration of the utility of these recommendations when they described the socially validated resolution of the PB of three children diagnosed with autism whose treatments were informed by analyses personalized from interviews. This type of analysis was then termed an IISCA (Jessel et al. 2016).

Rationale or Underlying Theory

A fundamental assumption in applying FA methodology is that PB is a learned or operant set of responses, ones that are maintained by their consequences. Certain events that are more likely to be experienced following PB than to be experienced in the absence of PB can serve to increase the future probability (i.e., reinforce) of PB. Certain events that enhance the value of those consequences (referred to as establishing operations [EOs]) and that signal their availability (referred to as discriminative stimuli [SDs]) join in the controlling relation referred to as a contingency. In other words, no matter how extraordinary PB may appear when exhibited by children with autism and related disabilities (e.g., attempts to bite, scratch, and punch others, or banging

one's head against hard objects), those responses are assumed to be sensitive to their consequences. The variability in the occurrence of those behaviors is thus related to the events that momentarily establish or abolish the value of those consequences and to the environmental cues that do or do not signal the opportunity for PB to generate those consequences.

For example, if a child with autism has a history of biting her father whenever she asks him to brush her hair, and that biting has reliably afforded her some respite from the hair brushing task, it may be the case that escape from the demand to complete that task is one of the reinforcers for her biting. Were that to be the case, one might consider the father's imposition of the demand to be an EO (i.e., an event that momentarily enhances the value of escape as a reinforcer) and the presence of the father to be an SD (i.e., a stimulus that signals an opportunity for the child to produce escape by biting). It would not be atypical for a father to assume that biting is a by-product of his daughter's autism, but the operant assumption and FA could reveal the simpler, more amenable controlling relation between the demands he imposes, her biting, and the contingent removal of those demands. By interviewing caregivers who have witnessed a great number of these PBs and the conditions under which they have occurred, an analyst can discover child-specific consequences that *may* be serving as reinforcement for the PB, as well as child-specific environmental events that seem to evoke the PB. By emulating these antecedent and consequent events in an analysis, the analyst may be able to *demonstrate* the influence of these events on PB.

Although there are hundreds of demonstrations of the influence of generic variables on PB (e.g., attention, escape, tangibles; Beavers et al. 2013; Hanley et al. 2003), caregiver descriptions of the contexts in which PB occurs are often complex, suggesting the influence of qualitatively rich contingencies unique to each individual (Bowman et al. 1997; see also Slaton et al. 2017). The IISCA assumes and emulates this complexity, and the interview is therefore a necessary starting

point in the assessment process. The qualitatively rich descriptions provided by caregivers inform the analysis so that each client experiences individualized conditions that closely emulate the typical context in which PB occurs.

Another assumption implicit in an IISCA is that controlling contingencies of PB are more likely to be composed of multiple contingencies operating simultaneously. There are multiple examples in the literature demonstrating the necessity of combining multiple contingencies to evoke (e.g., Dolezal and Kurtz 2010), reinforce (e.g., Call and Lomas-Mevers 2014), or maintain (e.g., Mann and Mueller 2009) PB in FAs (see Slaton & Hanley 2018 for a review of the nature and scope of synthesis in the analysis and treatment of PB). These analyses illustrated that a synthesis of variables may sometimes have a more powerful effect on behavior than its component parts. The holistic notion that whole contingencies have properties not present in their component parts and that whole contingencies are not always reducible to the study of the parts was evident in a participant from Hanley et al. (2014). The analysis revealed that PB exclusively occurred under conditions in which caregiver attention and toys were synthesized into a single reinforcement contingency. When isolated, attention and toys had no influence over PB (i.e., evidence of an interaction without main effects of each contingency). Slaton et al. (2017) provided additional demonstrations of this effect in which whole (synthesized) contingencies controlled behavior, but the same contingencies, when isolated, did not (see also Ghaemmaghami et al. 2015). There are also cases in which the suspected contingency for PB is inextricably synthesized, meaning that the consequent event being tested cannot possibly be broken down into component, isolated parts without fundamentally changing the nature of the contingency (e.g., Bowman et al. 1997; Eluri et al. 2016). Partly due to these analyses, suspected contingencies are usually synthesized in IISCAs.

Although the synthesis of variables in the IISCA precludes the ability to understand the

extent to which each individual contingency influences each PB topography in a single analysis, those who implement the IISCA favor the safety, speed, and consumer acceptability of the analysis over the need to understand the individual contributions of each contingency. Safety in IISCAs is partly achieved due to the synthesized contingency because when PB occurs in the analysis, it is essentially terminated through the provision of all possible reinforcers (Call & Lomas-Mevers 2014). The IISCA also engenders safety by combining all reported topographies of PB as well as their reported precursors into one large class of responses that will receive programmed reinforcement. For instance, if caregivers report that the most dangerous behaviors of SIB and aggression are to be analyzed and treated, but also indicate that their child reliably stomps her feet and whines before engaging in the more dangerous responses, all four of those responses will be eligible for reinforcement in the IISCA. By reinforcing the first emission of any member of the response class with all possible reinforcers, escalation of PB in the analysis is thwarted. This tactic not only minimizes escalation of PB and thereby promotes safety during the analysis, but it also does not appear to confuse interpretations regarding the variables controlling dangerous PB. A study by Warner et al. (2019) demonstrated that less dangerous responses reported to precede or co-occur with more dangerous forms were highly likely to be maintained by the same synthesized reinforcement contingency when all topographies were subjected to analysis. Inferences from open contingency classes and synthesized contingencies are therefore considered reasonable trade-offs for the lack of demonstration of control over each topography of PB or of the relevance of each component reinforcement contingency.

Goals and Objectives

The specific goals of the IISCA are to (a) demonstrate strong control of PB with a contingency that is composed of materials and

interactions described as related to PB in the initial caregiver interview, (b) obtain a stable baseline of PB from which to evaluate the efficacy of a function-based treatment, and (c) identify a motivating set of conditions in which to prompt and differentially reinforce important social skills with the same reinforcers that were shown to maintain PB. By controlling behavior with an ecologically relevant contingency, treatment is likely to have a good fit in the home, classroom, and community contexts in which PB was occurring. By obtaining a baseline, changes in the rate of PB can be quantified and connected to systematic changes in the treatment. By identifying a properly motivating set of teaching conditions, functional communication, delay and denial toleration, and cooperation with adult instruction can be expressly taught to individuals for whom typical social experiences have not yet yielded these skills (Hanley et al. 2014).

Assessment Participants

As of December 2019, there are roughly 189 published cases in which the IISCA procedures were applied, and 178 of them successfully demonstrated control over PB by a reinforcement contingency (see Coffey et al. 2020, for a recent review summarizing IISCA applications and outcomes). The cases included in these studies vary on (a) participant characteristics (e.g., age, language ability, diagnosis), (b) topographies of PB, and (c) settings in which the IISCA was applied.

At present, IISCA participants range in age from 1 to 35 years, with more male participants than female participants. The IISCA has proven efficacious with participants who show no verbal communication, engage in highly sophisticated speech, or display language profiles in between (e.g., can sign but cannot talk or can speak in one- or two-word utterances). The overwhelming majority of individuals for whom the IISCA was successfully applied had an autism diagnosis, but many of the individuals with autism had other comorbid diagnoses, and yet some other

individuals were differently diagnosed (e.g., attention deficit hyperactivity disorder, Fragile X syndrome, generalized anxiety disorder, intellectual disability). Additionally, the IISCA was conducted for some children without any formal diagnosis, but for whom PB was of major concern. The participant profile for which there are no data is typically developing adults.

Although the IISCA has predominantly been used to assess some combination of aggression, SIB, and disruptive behavior, other more idiosyncratic topographies have been successfully evaluated (e.g., elopement, flopping, inappropriate sexualized touching).

The IISCA has been applied primarily in specialized day programs and outpatient clinics. To a lesser extent, it has been applied in homes, residential programs, hospitals, and public schools (Coffey et al. 2020). Factors such as setting, type of PB, language ability, and diagnosis have yet to impede the ability of the IISCA to show PB's sensitivity to environmental contingencies.

Assessment Procedures

The IISCA begins with an open-ended, semi-structured interview (Hanley 2012) with those who regularly deal with the client's PB (i.e., relevant caregivers). Questions are asked regarding (a) the types of PBs and associated less dangerous behaviors, (b) the events that usually evoke these behaviors, and (c) the events that reliably follow the behaviors that lead to its abatement. The interviewer therefore attempts to identify potential (a) target responses to be reinforced in the test condition of the analysis, (b) situations to be presented in the test condition, and (c) reinforcers to be provided contingent on PB in the test condition and continuously in the control condition. Once the interview is complete, the analyst designs the IISCA to emulate caregivers' descriptions of events.

In the analysis, the analyst alternates between conditions in a multielement design, in which functional control over the suspected

reinforcement contingency may be shown with the participant serving as their own experimental control. Caregivers are present for the analysis, either as observers or implementers of the analysis. Feedback from the caregiver as to whether the context and interactions in the IISCA emulated typical circumstances is recruited. One 3-, 5-, or 10-min experience of a given condition constitutes a session. A common pattern of session alternation is control, test, control, test, test. The analysis often begins with the control condition. In the control condition, the client has non-contingent, continuous access to all of the suspected reinforcers for PB (e.g., toys, a tablet, adult availability and compliance, and the absence of demands). The analysis begins with the control condition to verify that PB will not occur under the conditions designed to eliminate all relevant establishing operations.

The test session begins in the same way that the preceding control session ended; the client has continuous access to all suspected reinforcers for PB. The analyst then presents the EO, which usually involves the simultaneous removal of any suspected positive reinforcers (e.g., toys, attention, ability to engage in stereotypy) and presentation of any putative aversive but routinely experienced events. Upon the first instance of any PB or associated less dangerous behavior, the analyst relents, removing any aversive stimuli (e.g., terminating demands) and delivering the suspected positive reinforcers, which essentially returns the client to the same conditions experienced in the control condition but for only 30 s to 1 min. The analyst then presents the EO again in the test session, and this process continues for a brief period, usually 5 min. Data on all PB types are measured and graphically depicted (data are typically plotted as a rate, i.e., PB per minute in each session). The analyst continues to rapidly alternate sessions until a clear difference in level, trend, and variability across test and control data paths is evident. A successful IISCA typically shows zero or near-zero levels of PB across control sessions and consistently elevated, but stable, rates of PB across test conditions (Jessel et al. 2016). If this outcome is not achieved within 45 min, then the IISCA is redesigned after

discussing the just witnessed behavior and additional interviewing.

Efficacy Information

Of the 189 published IISCAs in the literature, 178 were differentiated. Only a few authors have reported on how many iterations of the IISCA were necessary to produce a differentiated outcome, making it difficult to assess the extent to which IISCAs yield differentiated (useful) results on the first attempt. For example, Jessel et al. (2016) reported that 73% of cases (22 of 30) were initially successful. Within a consecutive-controlled case-series design, Slaton et al. (2017) reported that 100% of IISCAs (9 of 9) were initially successful (these authors also showed that standard analyses Iwata et al. (1982/1994) were successful across only 44% [4 of 9] of cases when applied to the same participants). More recently, Jessel et al. (2020) reported that 85% of cases (22 of 26) were initially successful.

Given that the IISCA process identifies unique contingencies through open-ended caregiver interviews, myriad types of synthesized contingencies have been demonstrated to be functionally related to PB. Many different combinations of social-positive, social-negative, and automatic reinforcement have been evaluated in a synthesized manner (e.g., escape from academic instruction to toys and unrestricted access to stereotypy), and the qualitative features of those contingencies vary across participants (i.e., that which clients escape from and to is often unique).

Considering that the ultimate goal of any FA is to design interventions that eliminate PB in relevant contexts with enduring meaningful effects, the treatment literature in which the IISCA was employed deserves mention. The IISCA has produced effective and socially meaningful outcomes in 100% of cases in which treatment was extended to relevant contexts and social validation of the outcomes was sought (i.e., implemented by relevant caregivers, in relevant settings, using practical schedules of reinforcement, e.g., Hanley et al. 2014; Jessel et al. 2018; Taylor et al. 2018). In Slaton et al. (2017), cases in which both types of

analyses – standard FAs and IISCAs – produced conclusive results were subsequently evaluated via a comparison of initial treatment effects. The authors found that treatments based off the IISCA were always successful in eliminating PB and developing a more appropriate replacement response for the learner, whereas treatments based off the standard FA were similarly successful in only half the applications.

Outcome Measurement

Five questions are considered when evaluating outcomes of the IISCA: (1) Does it produce a highly differentiated outcome (i.e., is strong control over PB shown in the IISCA)? (2) Is that outcome produced safely and quickly? (3) Do treatments designed from the IISCA yield efficacious outcomes (e.g., elimination of PB and acquisition of relevant skills)? (4) Are these efficacious outcomes successfully transferred to relevant people, contexts, and time frames? (5) Do treatments designed off the IISCA produce socially meaningful outcomes (i.e., is the amount of behavior change satisfying to caregivers)?

The 94% success rate of the IISCA in the literature suggests that it is highly likely to produce differentiated outcomes, providing robust evidence of the influence of personalized, synthesized contingencies on PB. Success in an analysis can be measured in myriad ways, but differentiation across test and control conditions is the basic requirement. Although it is possible that the documented success rate at present reflects a publication bias for demonstrations of functional control over behavior, the 100% success rates of the IISCAs reported in Jessel et al. (2018) and Slaton et al. (2017) – in which the consecutive-controlled case-series design was employed to explicitly address publication bias – speak to its efficacy.

Differentiated IISCA outcomes are achieved rapidly. According to Coffey et al. (2020), the median duration of published IISCAs is 25 min (range, 15 to 100 min), suggesting that the IISCA is a fast approach to analyzing PB. Recently, Jessel et al. (2019) demonstrated that IISCAs completed in as short as a single, 5-min session

could produce differentiation and could inform socially validated treatment outcomes.

The safety of IISCA procedures has yet to be quantified and measured, but the safety of an IISCA can be gleaned from the facts that (a) clients typically spend fewer than 30 min in the analysis, (b) PB is usually zero or near-zero in the control condition, and (c) the rate of PB in the test condition usually occurs around 2 per min, which, considering the length of the average reinforcement interval (e.g., 30 s), conveys that only single instances of PB often occur when an evocative situation is represented in test sessions. The unique commitment to the provision of *all* suspected reinforcers immediately following a single occurrence of *any* suspected member of the response class prevents escalation of PB once evoked. As opposed to reactive procedures like session termination criteria, these particular methods are the means by which participants, analysts, and caregivers are safeguarded in an IISCA.

Treatments explicitly designed to target the life skills of functional communication, toleration, and compliance with adult instruction have been highly efficacious in all cases when informed by an IISCA (e.g., Ghaemmaghami et al. 2016; Hanley et al. 2014; Jessel et al. 2018; Santiago et al. 2016; Slaton et al. 2017; Taylor et al. 2018). In addition, a few of those demonstrations extended their treatment to be implemented by relevant caregivers under relevant conditions (Hanley et al. 2014; Jessel et al. 2018; Santiago et al. 2016). All cases in which social validation was sought following the treatment development and extension process, it was achieved. The IISCA and subsequent skill-based treatment have been described as highly satisfactory processes with results that have improved the lives of the families for whom they were implemented.

Qualifications of Treatment Providers

The demonstrations of successful outcomes when using the IISCA in the literature have primarily involved implementation by a board

certified behavior analyst (BCBA[®]; www.bacb.com); however, it is encouraging to note that many of the IISCAs conducted in Jessel et al. (2016) and Slaton et al. (2017) were done so by relevant caregivers or teachers under the supervision of a BCBA. FAs require a sound understanding of the principles of learning derived from the field of behavior analysis. They also require the skills to naturally and systematically interact with a child or client in an attempt to emulate their ecology, repeatedly evoke and deescalate PB, and therefore understand PB in a scientific sense. It is recommended that an individual with little or no training in applied behavior analysis not undertake this procedure or only do so with some specific training or supervision of a BCBA.

Intestinal Permeability Studies

Ann Reynolds

Pediatrics, Child Development Unit, Aurora, CO, USA

Definition

Intestinal permeability (IP) refers to the degree of “leakiness” of the intestinal mucosal barrier. The intestinal epithelium regulates the movement of fluids and electrolytes into and out of the gut. It also serves as a barrier to foreign antigens and toxins.

Historical Background

Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder characterized by deficits in social reciprocity, disordered language, and restricted interests and/or repetitive behaviors. Gastrointestinal dysfunction has been reported in 9–51% of children with ASD, with a lifetime prevalence as high as 70%. Children with ASD have been noted to have diarrhea, constipation, gastroesophageal reflux (GER), and abdominal pain. Dietary restriction is common, and up to 33% of families try a gluten- and casein-free (GFCF) diet to address GI symptoms with hopes of improving the behavioral symptoms of ASD. Advocates of the GFCF diet postulated that gluten and casein proteins are incompletely broken down in the intestine, absorbed by a leaky gut, and become “neuroactive peptides” that contribute to the symptoms of autism. Urine peptide analyses in people with ASD collected in the 1990s initially identified compounds that were felt to be opioid peptides found in gluten and casein. The hypothesis arose that these compounds were absorbed across a “leaky gut.” Subsequent studies using newer techniques of mass spectroscopy could not confirm that there were increased amounts of these peptides in the urine of people with ASD. Intestinal permeability has been found to be

increased in many medical conditions including gastrointestinal disorders such as celiac disease, autoimmune disorders such as diabetes, and atopic diseases such as eczema.

Current Knowledge

The intestinal barrier is important for protection from infection and also to maintain tolerance to most of the antigens that the gut is exposed to. Tight junctions are important in regulating movement of water, nutrients, and immune cells between intestinal cells (Lu et al. 2000). The majority of proteins that could result in immune activation cross the intestinal barrier by going through the cells. During this process, the proteins are degraded into smaller, less immunogenic peptides. The rest cross as intact proteins between the cells. When the tight junctions are disrupted, a large number of immunogenic proteins may cross the mucosal barrier, and it is hypothesized that an immune response may develop (Clemente et al. 2003). Increased intestinal permeability has been implicated in the development of type 1 diabetes in individuals who are genetically predisposed. Another study found increased IP in individuals with food allergy and food hypersensitivity (Ventura et al. 2006).

Intestinal permeability (IP) is typically measured by drinking two sugars and measuring their excretion in the urine. One is a large disaccharide such as lactulose that is absorbed from the gut via a paracellular (between the cells) pathway. The other is a smaller monosaccharide such as mannitol which is absorbed from the gut mainly via a transcellular (through the cell) pathway. If the junctions between intestinal epithelial cells are intact, less lactulose will be absorbed and excreted in the urine. If the intestine is more permeable or “leaky,” more lactulose will be absorbed via the paracellular pathway, leading to a higher lactulose to mannitol ratio in the urine.

Five studies have evaluated intestinal permeability in individuals with ASD (D’Eufemia et al. 1996; de Magistris et al. 2010; Horvath and Perman 2002; Kemperman et al. 2008; Robertson et al. 2008). D’Eufemia found abnormal intestinal

permeability in 9 of 21 children with high-functioning autism without gastrointestinal symptoms, compared to control subjects (D’Eufemia et al. 1996). Horvath et al. (2000) also found increased permeability in 19 of 25 children. Kemperman (2007) did not find elevated permeability in 21 children with pervasive developmental disorder, and Robertson et al. (2008) also did not find a difference in IP in 14 children with autism and GI symptoms compared to 7 sibling and 8 typical controls. None of these studies used research-reliable diagnoses of ASD. Horvath and Kemperman did not use control groups. Only D’Eufemia addressed asthma and eczema symptoms as a potential confounding variable. de Magistris et al. (2010) found abnormal IP in 37% of 90 subjects with autism, 21% of 146 first-degree relatives, and 5% of controls. The difference was significant with a p value <0.0001 . Twenty-five percent of the children with ASD were on a gluten-casein-free diet. Those children had a lower IP than those on a regular diet, $p = 0.034$. They did rule out celiac disease but did not get a history of allergy/atopy. They noted no difference in GI symptoms in the group with abnormal IP compared to the group with normal IP. In that study, increased permeability seems to function as an endophenotype (a phenotype/characteristic that is found in unaffected family members at a higher rate than the general population and felt to possibly increase the risk of developing the disease). While the most recent study (de Magistris et al. 2010) of intestinal permeability in children with ASD did have a well-characterized sample with adequate controls, the authors point out that there has been no evidence that increased permeability is associated with neuropsychiatric manifestations or even gastrointestinal disorders. A recent review of gastrointestinal issues in children with ASD agreed with this point as well (Buie et al. 2010).

Future Directions

Future studies should evaluate the impact of increased permeability on health and neuropsychiatric outcomes. It is plausible that embryologic insults may impact development of intestine and

brain, and it is also plausible that genetic disorders alter function in both gastrointestinal and central nervous systems. Studies investigating the immunologic and microbiologic environment of the intestine are ongoing.

Intimate Relationships and Dating

Anthony Burns¹ and Rachel Loftin²

¹Department of Psychiatry, AARTS Center, Rush University Medical Center, Chicago, IL, USA

²AARTS Center, Rush University Medical Center, Chicago, IL, USA

Definition

Intimate relationships, including marriage and long-term dating relationships, are close relationships that include physical and/or emotional intimacy. Typically, intimate relationships have a sexual component. There has been limited research on intimate relationships in autism spectrum disorder (ASD), but it appears that people with ASD may have more difficulty achieving intimate relationships than typically developing people. Certainly, some autistic people marry, but it appears that many people with ASD do not achieve the intimate relationship they desire.

Historical Background

Historically, sexuality was regarded as a taboo topic within the content of developmental disabilities and autism. For years, our knowledge about

sexuality and sexual expression in this population was limited by our reliance on caregiver reports describing institutionalized sample populations. By relying on these samples, the field ran the risk of reporting inaccurate rates of sexual behavior, attraction, and identity (Hellemans et al. 2007; Stokes and Kaur 2005; Haracopos and Pedersen 1992). For instance, the prevalence of asexuality, or the lack of sexual interest or desire for a sexual relationship, is reported by some early studies to be significantly higher in ASD than in the general population. In many studies, particularly older studies, the data on sexual activity among people with ASD were collected via parent report, which may not be accurate.

Current Knowledge

Sexuality, by definition, is a social activity. There appear to be minimal differences in physical maturation between typically developing individuals and those with ASD.

Differences in social reciprocity, social communication, and ability to develop interpersonal relationships – inherent in ASD – surely affect sexuality (Nichols and Blakeley-Smith 2009), and research suggests that higher levels of ASD traits are associated with greater loneliness and fewer and lower quality relationships (Jobe and White 2007). Deficits in social cognition may have particular impact. Perspective taking, or theory of mind (ToM), is crucial in understanding the thoughts, feelings, and behaviors of other people and helps individuals successfully navigate social situations (Doherty 2008). Individuals with autism often display underdeveloped ToM, and have trouble taking other's perspectives (Baron-Cohen et al. 1985; Frith and Happé 1994). It is understandable then that despite their desire to have social relationships, individuals with autism report experiencing higher rates of loneliness than their peers and having fewer friendships (Jobe and White 2007; Bauminger and Kasari 2000). Because theory of mind is essential for understanding social situations, individuals with ASD can

misattribute other's intentions and endorse negative social biases about themselves or others (Blackshaw et al. 2001; Barnhill 2001; Van Roekel et al. 2010). To further understand social deficits in autism, it is imperative that comorbid psychopathologies, like social anxiety (one of the most common comorbid disorders within the ASD population), be taken into consideration (White et al. 2009; Simonoff et al. 2008).

The presence of autism can interfere with the social and cognitive processes under development during puberty, often resulting in a mismatch between a person's physical readiness for sexual intercourse and the individual's socio-sexual understanding required to appropriately engage in these behaviors. Given social and cognitive deficits, it may be hard for children to actively engage with peers, thus reducing their reliance on peers for learning "proper" skills for engaging in social and romantic relationships (Stokes et al. 2007). Despite these difficulties, however, many individuals with ASD express interest in developing and participating in these types of relationships, as well participate in solitary sexual behaviors, like masturbation (Hellemans et al. 2007, 2010; Haracopos and Pedersen 1992; Van Bourgondien et al. 1997; Ousley and Mesibov 1991; Gilmour et al. 2012).

There may be some difference in the type of relationship that a person with ASD pursues. In recent years, studies assessing the identity and behaviors of those actually diagnosed with ASD have found mixed results regarding sexual orientation identification, with some reporting higher sexual minority rates within the community, while others suggest heteronormative sexual interest (Byers et al. 2013; Gilmour et al. 2012; Fernandes et al. 2016). Despite these advances in understanding socio-sexual development, there is still much to learn about the formation of intimate relationships and dating behaviors of individuals with autism.

Future Directions

More and better research to understand perspectives of people with ASD, their sexual behavior,

identification, and attraction is essential to developing interventions to support healthy relationship development. Investigation into the connection, if any, between transgender identity and autism is needed. Anecdotal and emerging empirical evidence suggests a higher rate of trans identity among people with ASD. We do know that trans youth are at risk of bullying, social rejection, and psychopathology, and it is important for ASD providers to be aware and sensitive to the needs of this subset of the ASD population.

Sex education and instruction in intimate relationship development is another domain where more research is needed. Little research has been done to investigate effective sex education programming, yet a number of recent publications offer tips for dating “on the spectrum.” It will be useful to evaluate curricula for dating skills, sex education programs, and implications for people with ASD. For instance, one investigation (Roth and Gillis 2015) looked at use of online dating among people with ASD and found safety concerns.

As methods of social cognitive skills instruction advance, the application of these skills to developing intimate relationships will be an important area of investigation.

Intonation

Lisa Edelson-Fries
Department of Psychology, Boston University,
Boston, MA, USA
Neurocognition, Department of Brain Health,
Nestlé Institute for Health Sciences, Lausanne,
Switzerland

Synonyms

[Prosody](#); [Tone of voice](#)

Definition

Intonation refers to the melodic patterns of the voice which are not used to differentiate words. It can be used to indicate the function of a sentence (e.g., statement, question, sarcastic comment), the speaker’s affect, or to emphasize important topics in a conversation. Individuals with autism spectrum disorder often have atypical intonation patterns, either using little intonation, resulting in a flat or robotic sound, or using exaggerated intonation, which can sound unusual as well. These characteristic intonation patterns can be diagnostic markers for autism spectrum disorder.

Intraverbals

Geralyn Timler
Speech Pathology and Audiology, Miami
University, Oxford, OH, USA

Definition

Intraverbals are a listener's verbal responses to another speaker (Skinner 1957). These responses include answers to questions (e.g., a speaker asks, "Where are you going?" The listener replies with an intraverbal, "Home.") and responses to comments (e.g., a speaker says, "I like that one." The listener replies with an intraverbal, "Me too." or "I don't like it."). Intraverbal behaviors are an important component of reciprocal (back-and-forth) social communication (Mudford et al. 2009). Social communication is most effective when, individuals respond appropriately to each other's questions and comments.

Introduction to the Delis Kaplan Executive Function System

Kathryn A. Simon
Yale Child Study Center, New Haven, CT, USA

Synonyms

[D-KEFS](#)

Description

The Delis-Kaplan Executive Function System (D-KEFS) consists of nine individual tests designed to assess aspects of executive function skills in children and adults ranging from age 8 to 89. Executive function (EF) skills are the mental processes that enable individuals to regulate their thoughts and behaviors. Specific EF skills include planning, focusing attention, remembering instructions, and switching between multiple ideas or tasks successfully. The Center on the Developing Child at Harvard University (2011) likens executive functioning to the brain's "air traffic control system," positing that, like the control center at a busy airport coordinating arrivals and departures, the brain relies on executive function skills to filter distractions, prioritize tasks, set and achieve goals, and control impulses. These discreet skills serve as the foundational cognitive resources for aspects of daily functioning including academic, cognitive, and social functioning.

The D-KEFS measures two general types of executive functioning skills including fundamental cognitive skills (e.g., attention, perception, and language) along with higher-level cognitive processes (e.g., concept formation, inhibition, planning, and cognitive flexibility). The tests that comprise the D-KEFS facilitate a cognitive process approach allowing for the examination of fundamental component skills along with their contributions to higher-order cognitive processes.

Introduction to the Delis Kaplan Executive Function System, Table 1 D-KEFS test description and associated EF skills

D-KEFS tests		
Test	Description	Executive functions tapped
Word context test	Requires the examinee to use verbal cues to deduce to meaning of made-up words	Deductive reasoning Integrating multiple pieces of information Generation (i.e., hypothesis testing) Cognitive flexibility (switching)
Sorting test	Requires the examinee to repeatedly sort and describe a set of cards based on attributes of shape, color, writing, or word meaning. The second part of this test requires the examinee to describe examiner created sorts	Verbal conceptual reasoning Nonverbal conceptual reasoning Generation Cognitive flexibility Inhibition
Twenty questions test	Requires examinee to look at an array of pictures and ask up to 20 yes/no questions to guess which picture the examiner has chosen	Establish/maintain cognitive set (working memory) Monitoring Category recognition Ability to use feedback (correct) Inhibition Planning (i.e., formulate abstract yes/no questions that eliminate the maximum number of objects)
Tower test	Requires examinee to rearrange a set of disks placed on rods to match a predetermined arrangement. The examinee must keep in mind several rules while completing the task	Spatial planning Monitoring Inhibition Cognitive flexibility Establish/maintain cognitive set
Color-word interference test	Requires examinee to: <i>Condition 1:</i> Name colors <i>Condition 2:</i> Read color words <i>Condition 3:</i> Look at color names that are printed in different color inks (e.g., the word “red” in blue ink) and name the color of the ink instead of reading the word <i>Condition 4:</i> Switch between reading the ink color and reading the color word	Monitoring Inhibition Cognitive flexibility Establish/maintain cognitive set
Verbal fluency test	Requires examinee to generate words by first letter, by category, and then by alternating between two categories	Verbal knowledge Systematic retrieval of lexical items Monitoring Cognitive flexibility Establish/maintain cognitive set
Design fluency test	Requires examinee to create unique designs among series of dots using specified number of straight lines. Dots are either filled or empty, and the task builds from single fills (only empty or only filled) into a switching task of between filled dots and empty dots	Cognitive flexibility Monitoring Inhibition Establish/maintain cognitive set
Trail making test	Requires examinee to create a trail with their pencil by connecting numbers, letters, and then alternating numbers and letters. A measure of connecting dots (motor speed) is also included	Cognitive flexibility Inhibition Establish/maintain cognitive set
Proverb test	Requires examinee to interpret proverbs	Verbal abstract thinking Semantic integration Generalization

Each of the nine individual tests taps numerous executive functioning skills (see Table 1 for test descriptions and associated EF skills assessed),

and most involve the administration of multiple conditions. Thus, each test provides a wide spectrum of cognitive variables including measures of

component skills, problem-solving strategies, temporal aspects of response patterns, ratio measures, and various error types. Values obtained across these measures compare an individual's performance to the normative sample for a particular indicator and can assist clinicians in two important ways. First, the D-KEFS allow for the documentation of an individual's unique profile of spared and impaired executive functions. Second, they can support the identification of the neurocognitive mechanisms that underlie an individual's deficient performance by noting patterns of performance across tasks. Performance on these tasks can be impacted by skill deficits at any stage of cognitive processing from lower-level basic skills to higher-level cognitive functions (Delis et al. 2001a).

The D-KEFS tests are considered useful indicators of executive functioning skills for a variety of reasons. They are notable for their sensitivity to detect even mild vulnerabilities in EF skills offering "lower floors" and "higher ceilings" as compared to previous versions of similar tasks (Delis et al. 2001a). The developers have paid particular attention to the measurement of skills that would indicate frontal lobe involvement (e.g., attention and inhibition). Design features also include the incorporation of "switching conditions" across the various subtests that allow multiple opportunities to assess cognitive flexibility or the ability to shift between sets (e.g., rules, categories, or response sets). Additionally, the presence of "capture stimuli" is embedded across multiple tasks to pull for concrete stimulus-bound responding allowing for the detection of basic impulse control deficits. Finally, the testing procedures gradually increase the processing demands placed on an individual, allowing examiners to detect patterns of responding and thresholds of stimulation that appear to be best tolerated by an individual (Delis et al. 2001a). For example, an individual might have greater difficulty on more basic tasks but demonstrate improved performance as the level of challenge and stimulation increases. Such individuals require a high degree of cognitive stimulation to recruit their most effective EF skills. In contrast, for another individual, performance may decline as task complexity increases indicating deficits in more fundamental cognitive skills.

The ability to detect such patterns of performance provides insight into the cognitive processes of individuals and is instrumental for both diagnosis and the development of targeted interventions to improve functioning.

Historical Background

The nine tests composing the D-KEFS represent a combination of tests developed by authors Edith Kaplan and Dean Delis along with their adaptations of tests developed from long-standing clinical instruments and procedures implemented in past experimental studies (Delis et al. 2001a; Homack et al. 2005). Two of the nine tests were developed by the D-KEFS authors. The Word Context Test was designed by Edith Kaplan in the 1940s. Working in collaboration with the developmental psychologist Heinz Werner, Kaplan developed the test to study young children's acquisition of word meanings (Werner and Kaplan 1952). For the present D-KEFS battery, the authors adapted the original version to offer a suitable assessment tool for use with both children and adults. The precursor to the D-KEFS Sorting Test was developed by Dean Delis in the late 1980s (Delis et al. 1995) in the form of the California Sorting Test. This test was later revised to increase the tool's sensitivity and complexity by incorporating more sorting concepts across multiple sets of cards.

The seven remaining D-KEFS tests are modifications of tests developed by authors other than Dean Delis or Edith Kaplan. For example, the Color-Word Interference Test is a modification of the classic Stroop test developed in the 1930s (Stroop 1935). The basic paradigm of the Stroop test compares an individual's performance on a basic task (e.g., reading names of colors) to their performance on an analogous task in which a habitual response needs to be suppressed in support of an unusual one (i.e., naming the ink color that incongruously named color words are printed in). Many different Stroop test versions have been developed over time (e.g., Comalli et al. 1962; Golden 1978), with variations in the color and number of the test items, the number of subtests, and the administration procedure. Delis and

Kaplan increased the complexity of the original task by developing a series of conditions (see Table 1) that allow for both the measurement of basic naming skills as well as complex cognitive flexibility and inhibitory skills creating increasingly difficult conditions in which individuals must alternate between reporting the word written on the page and the color of the ink.

In a similar vein, the Twenty Questions Test is a modification of a popular guessing game often played by children or adults in which an individual must pose a series of yes/no questions in order to identify an unknown entity. The task was first used as a test procedure for youth in the 1960s (see Baron 2004). It has been modified by Delis and Kaplan to provide systematic means of isolating specific skill deficits and identifying the strategies individuals employed to engage in such higher-level problem-solving tasks. For the D-KEFS version, the authors designed a page with pictures of 30 stimuli that requires the examinee to ask questions that eliminate as many stimuli as possible so that a target stimulus can be correctly identified.

The Tower Test is also a modification of earlier tasks used in experimental studies. This D-KEFS test is similar to earlier Tower Tests (e.g., Tower of Hanoi; Welsh 1991, Tower of London; Anderson et al. 1996). Among the modifications, the D-KEFS version adds process measures such as first move completion time, total number of moves, item completion time, final achievement, and number of rule violations.

A description of each test's origin and history is beyond the scope of the present chapter but can be found in the D-KEFS Examiner's Manual (Delis et al. 2001a) as well in a detailed review of the measure published by Ida Sue Barron (2004).

Psychometric Data

The D-KEFS was standardized on a nationally representative sample and stratified sample of 1750 children, adolescents, and adults, ages 8 to 89 years (Delis et al. 2001b). Stratification was

based on the 2000 US Census figures and considered age, sex, race/ethnicity, years of education, and geographic region (Delis et al. 2001b). D-KEFS normative data for each measure were analyzed for age trends, including error measures and scores presented in cumulative frequency distributions. According to the authors, the age effects were evaluated using linear and nonlinear regression techniques. In general, children from the younger age groups (8–10 years) and adults from the oldest age groups (70–89 years) tended to obtain lower raw scores on the D-KEFS executive function measures as compared to examinees from the adolescent, young adult, and middle-aged groups. D-KEFS variables that measure more fundamental verbal skills (e.g., verbal fluency measures) tended to be associated with steep rises in raw scores across the younger age groups, but there was a slower decline in the older age groups (Delis et al. 2001a). Performance on measure that is highly dependent on speed of processing tended to peak in the adolescent and young-adult groups, whereas performance on tests of verbal conceptual reasoning tended to peak in the adult age group. These trends strengthen the construct validity of the D-KEFS, as performance across age ranges is consistent with literature on developmental cognitive processes and the trajectories of skill development across domains over the life course (Delis et al. 2001b). In general, the standard deviations of the D-KEFS measures tended to be larger in the youngest and oldest age groups than in the adolescent, young-adult, and middle-aged groups. For children, these findings are consistent with variable rates of development of cognitive skills, including EF. For elderly adults these finding may reflect variability in the normal aging process and/or subclinical neurological processes (Delis et al. 2001b).

Reliability

Reliability indicators including internal consistency, stability coefficients, and alternate form reliability, which established standard error of measurement and confidence intervals, are

presented by the test developers (see Delis et al. 2001a). Test-retest reliability was estimated with an average time between administrations of 25 days. The majority of the test-retest coefficients scores fell in the moderate range and varied substantially across tests. Twenty Questions (0.24 to 0.43) and Design Fluency (0.32 to 0.58) were among the lowest estimates, whereas Word Context (0.70) and Proverb Test (0.76) were among the highest. Measures of internal consistency also varied considerably across the individual tests and within individual tests based on age groups and testing condition. Some of the lowest internal consistency values were observed on the Twenty Questions Test (0.10 to 0.55 across age groups), while the highest values observed on the Color-Word Interference Test (0.62 to 0.86), Verbal Fluency Test (0.32 to 0.90), and Trail Making Test (0.57 to 0.81). In a critique of the measure, Schmidt (2003) noted that only 17% of the reliability values published in the D-KEFS manual were above a 0.80 value. However, the authors maintain that such values are to be expected based on the task complexity and multifaceted nature of EF skills (Delis et al. 2004).

Validity

The D-KEFS manual provides few validity studies, focusing primarily on clinical evaluations performed on samples of patients with Alzheimer's or Huntington's disease. The test manual suggests that validity for many of the tests had been previously established as they were modified from preexisting measures with proven validity.

Subsequent studies have demonstrated that D-KEFS tests are sensitive to the assessment of executive function deficits in numerous clinical populations including patients with focal frontal lobe lesions (Baldo et al. 2004); multiple sclerosis (Beatty et al. 1995); normal aging (Wecker et al. 2000); autism spectrum disorders (Kleinhans et al. 2003); schizophrenia (Beatty et al. 1994); childhood stroke (Nichols et al. 2003); attention deficit disorder (Donnelly et al. 2001); and fetal alcohol syndrome (Schonfeld et al. 2001).

Clinical Uses

D-KEFS tests allow examiners to systematically generate and evaluate relevant clinical hypotheses related to the executive functioning of a given examinee by comparing and contrasting performance on multiple testing conditions and using contrast measure scores and error analyses. A review of the administration, scoring and interpretation, test construction, standardization, and technical adequacy indicates that the D-KEFS has been useful as both a clinical instrument as well as a research tool for increasing knowledge of the frontal lobe functions (Homack et al. 2005).

The D-KEFS is notable for its utility in assessing and diagnosing strengths and vulnerabilities for both youth and adults in the domains of planning, impulsivity/inhibition, abstract thinking, and problem-solving. It has been particularly useful among clinical populations including those with traumatic brain injury, attention deficit disorders, and autism spectrum disorder as well as dementia and Alzheimer's among older adults (Delis et al. 2004; Homack et al. 2005). In addition to assisting with diagnostic clarity, the tool is useful in supporting clinicians in planning rehabilitation programs and interventions tailored to an individual's profile of executive function strengths and weaknesses.

Irritability in Autism

Denis G. Sukhodolsky¹, Theresa R. Gladstone²
and Carolyn L. Marsh²

¹Child Study Center, Yale School of Medicine,
Yale University, New Haven, CT, USA

²Yale Child Study Center, New Haven, CT, USA

Irritability in children with autism spectrum disorder (ASD) has been a long-standing target of clinical research including pharmacological and behavioral interventions. Historically, the term irritability was used in ASD literature as an umbrella category for severe disruptive behaviors including temper tantrums, aggression, and non-compliance. The rates of co-occurrence of ASD

with disruptive behavior disorders ranges from 16% to 37% for oppositional defiant and 2–9.6% for conduct disorder. However, up to 65% of children with ASD can have physically aggressive behavior towards their peers or caregivers. (Kanne and Mazurek 2011). Using a more recent conceptualization of irritability, as a cluster of mood symptoms, 45% of children with ASD were reported to have high levels of angry mood and temper tantrums (Mayes et al. 2017). Irritability and associated behavioral problems are distressing in their own right for children and families, and they also contribute to the gap between adaptive functioning and mental age beyond the impairment conferred by ASD (Williams et al. 2006).

Regarding causal mechanisms, irritability may be related to the core symptoms of ASD as well as to the psychosocial and biological mechanisms common across psychiatric disorders. In children with ASD, anger outbursts might be uniquely associated with the inability to communicate effectively, the interruption of repetitive behaviors, or visual, auditory, or tactile sensory sensitivities (Kanne and Mazurek 2011; Reese et al. 2005). Age and cognitive functioning can impact the type and frequency of disruptive behavior problems. For example, temper tantrums decrease with age, and self-injurious behaviors are more common in children with intellectual disability. However, the rates of aggressive behavior and noncompliance were similar in children with ASD with or without cognitive impairment (Mayes et al. 2012).

There can be differences in the expression of anger and triggers of disruptive behavior in children with ASD compared to children only with conduct disorder. For example, anger outbursts in ASD have been described as “immature” with labels such as “meltdowns” being used to reflect the uncontrollable nature of these behaviors. Also, physical aggression in ASD usually lacks hostile intent but is often impulsive in nature and can result in injuring people or destroying property (McDougale et al. 2008). However, irritability and aggression in ASD are also likely to share some common mechanisms with other forms of developmental psychopathology. For example,

the role of positive and negative reinforcement of aggressive behavior in the context of aversive parent-child interaction has been well studied in developmental psychopathology and provided a foundation for parenting interventions for aggression in children with and without ASD.

It is also important to recognize that temper tantrums and rough and tumble play can be developmentally appropriate and various facets of the anger experience and expression may follow different developmental trajectories. Thus, temper tantrums that include crying, stomping, pushing, hitting, and kicking are common in 1- to 4-year-old children and range in frequency from 5 to 9 times per week with the average duration of 5–10 min (Potegal et al. 2003). The intensity and number of tantrums tend to decrease with age although typically developing children continue to outwardly display anger and frustration, behaviors that parents often label as tantrums. This decrease in the frequency of temper tantrums as children age is paralleled by the development of emotion regulation skills and the acquisition of socially appropriate ways to express anger (Blanchard-Fields and Coats 2008). In children with ASD, if temper tantrums and disruptive behavior are present in childhood, they are likely to persist and may escalate in up to one third of adolescents (Shattuck et al. 2007; Simonoff et al. 2013). Aggression and irritability continue to cause significant distress to many adults with ASD and their families and present considerable challenges for clinical care (Siegel et al. 2014).

Following the seminal studies of risperidone for serious behavioral problems in ASD, the Irritability Subscale of the Aberrant Behavior Checklist (Aman and Singh 2017; Aman et al. 1985) has emerged as a gold standard in clinical trials and has been used as a measure of treatment effects in over 120 studies. The 15-item Irritability Subscale includes questions about aggression, self-injury, tantrums, agitation, and unstable mood. The total Irritability Scale score ranges from 0 to 45, with higher scores indicating greater severity. Other measures that have been used to characterize irritability and disruptive behavior in children with

ASD include the disruptive behavior subscales of the Child and Adolescent Symptoms Inventory (Gadow et al. 2008) and more recently, the Affective Reactive Index (Stringaris et al. 2012). Although most studies of irritability in ASD relied on caregiver-rated measures, there is emerging evidence that verbally able children with ASD can provide reliable self-reports of anger and irritability (Patel et al. 2017).

Interventions commonly used for children with ASD include psychotropic medications, psychosocial treatments, and special education programming (Volkmar et al. 2014). The goals of treatment include decreasing the core symptoms of ASD, enhancing specific communication and socialization skills, and reducing problematic behaviors. Atypical antipsychotics, risperidone and aripiprazole, have been reported to reduce irritability in children with ASD (Fung et al. 2016). However, medication side effects, most notably weight gain, metabolic abnormalities (McDougale et al. 2008), and high relapse rate when medication is discontinued (RUPP Autism Network 2005) underscore the value of non-pharmacological treatments for irritability in ASD.

Regarding behavioral interventions for irritability in ASD, applied behavioral analysis (ABA) has been a mainstay for reducing challenging behaviors and developing adaptive behavior skills in younger children with ASD and in children with ASD complicated by cognitive disabilities (Vismara and Rogers 2010). ABA identifies common sources of environmental reinforcement or functions of challenging behaviors in individuals with ASD such as attention from others, escape from task demands, access to preferred items or activities, and automatic or “self-stimulatory” reinforcement (Hanley et al. 2003). Knowledge of the function of challenging behavior is used to design behavior intervention plans that are based on modifying the reason why the behavior occurs in the child’s everyday life. In many forms of behavioral treatments for ASD parents are taught behavioral strategies of reducing disruptive behavior by modifying its antecedents and

consequences (Smith et al. 2000) and increasing compliance (Ducharme et al. 2007). A recent meta-analysis reported eight randomized studies of PMT for children with autism with an average effect size of 0.59 (Postorino et al. 2017). One approach to PMT was developed to address common and unique manifestations of irritability in ASD by enhancing standard PMT techniques with functional analysis, visual schedules for routine events, and teaching communication and daily living skills (Johnson et al. 2007). A randomized trial of 124 children, ages 4–13, with ASD tested this program in a comparison of risperidone alone to risperidone plus PMT and revealed greater reduction of disruptive behavior and lower drug dose in the combined condition (Aman et al. 2009). A recent study tested a preschool version of this program in 180 children with ASD, ages 3–7, relative to a parent education control condition and demonstrated significant reductions in parent-rated irritability and noncompliance in the active treatment condition (Bearss et al. 2015).

Historical Background

For several decades, from the early days of Israel's independence in 1948 up until the late 1980s, the care of children as well as adults with autism spectrum disorder (ASD) was the sole responsibility of the Israeli Ministry of Health. During this period, there were neither care centers nor residencies specifically designated for individuals with ASD. Instead, they were mostly referred to general psychiatric hospitals, which lacked specialized treatment modalities to meet these individuals' needs, particularly the distinct needs of children, adolescents, and young adults with ASD.

The early steps towards establishing specialized responses to the needs of individuals with ASD in Israel originated in the late 1960s. At that time, in the absence of a comprehensive national policy in the field, local medical institutions' initiatives led to the establishment of a few preschool day-care units to address the needs of children with ASD. In 1974, parents of individuals with ASD established the Israel Society for Autistic Children (ALUT). In 1977, this group of parents was instrumental in urging the municipality of Tel Aviv to found the first school for children with ASD, called Yachdav (Togetherness).

The late 1980s and early 1990s were marked by important developments in professional awareness and policy principles for services targeting Israeli individuals with ASD and their families. It

was then that the Israel Ministry of Health recognized the need for care centers to serve the adult population with ASD in Israel. As a result, in the early 1990s, a modest multiple-agency initiative was taken to create community-based ASD care centers nationwide that would address the unique needs of individuals with ASD throughout the lifespan, from infancy to adulthood. This initiative comprised a comprehensive and holistic approach for delivery of medical, educational, and rehabilitative social services to individuals with ASD. This approach was facilitated by the collaboration of the Ministries of Education, Health, and Welfare and by local authorities and third sector nongovernmental organizations (NGOs).

Likewise, in 1990, professionals and public representatives established the Association for Children at Risk (ACR). This NGO's aim was, primarily, to advance an integrative model for early diagnosis and intensive community-based treatment and education in preschools and kindergartens serving children with ASD. This model was implemented in Tel Aviv and then in a step-wise fashion in the Tel Aviv metropolitan area. The cumulative experience gained by these integrative kindergartens served as the foundation for the later governmentally approved 14-hour-per-week therapeutic basket of services allocated to these children.

Following such clinical, educational, and public health developments in the field of community-based service delivery to individuals with ASD, in 1993 an official ministerial committee stated that "Autism is not a psychotic disorder, but rather a developmental disability that needs to be treated at multiple levels by multiple government offices." The committee also clearly defined these interministerial responsibilities and interrelationships. In turn, each ministry then established a designated unit to develop its specific responses and direct its work in this rapidly developing field. Furthermore, in 1998, the Ministry of Health issued professional criteria to define preschool children's eligibility for a community-based 14-hour therapeutic service basket for children with ASD. The Ministry of Health assigned responsibility for this basket's delivery,

supervision, and monitoring to its Department of Mental Health. Other general medical and mental health services are rendered by the non-governmental national healthcare system that operates under the National Insurance Law (see further below) through medical insurance organizations (the Israeli equivalent of HMOs in the USA).

In 2001, a new parents' organization, the Israeli Asperger Association (Effe), was established in order to advocate for the unique needs of high-functioning individuals with ASD.

In conclusion, since the 1980s, the services available in Israel for individuals with ASD across the lifespan have started to grow and improve. Yet, specifically regarding preschool children with ASD, who were at the focus of professional and public concern, these changes never matched the growing demand for services. In 1995, health policy planners predetermined a fixed budgetary allocation for the total annual number of therapeutic baskets to be delivered in Israel, allotting an annual quota increase of up to 40 preschoolers. However, the following 15 years witnessed a general upsurge in the worldwide prevalence of the ASD diagnosis, as exemplified in the USA by an increase from ≈ 3 in 10,000 in the 1980s (Burd et al. 1987) to ≈ 1 in 68 in recent epidemiological studies (Christensen et al. 2016). In view of the growing prevalence of ASD in Israel, public professional representatives (ACR) approached governmental and judicial authorities (2006), who responded by abolishing the aforementioned restrictive quota and thus ensuring universal eligibility for the therapeutic basket to all preschool children with ASD in Israel. Consequently, services for these children have widely expanded and improved nationwide.

To this day, consistent efforts are being made at the national level in Israel to raise awareness and improve early diagnosis and treatment that would promote intensive early intervention, thereby fostering improved prognoses for individuals with ASD. As seen in the section below on current services, treatments, and centers, the overall improvement noted in ASD services throughout the country has resulted from successful collaborations between various government ministries,

local authorities, parents' organizations, and professional NGOs. Yet, there is much more to be done in the areas of eligibility for services and service development for adults and elderly people with ASD.

Legal Issues

Legislation on the rights of individuals with ASD and their families in Israel culminated in the following fundamental laws, among others:

1. 16th Amendment (1984) to the Compulsory Education Law (1949) – granting the fundamental right to education also to children aged 3–5 years.
2. Special Education Law (1988) – defining among others: (a) the pedagogical and paraprofessional basket for special education and (b) the school placement committee at the local authority level (e.g., members, procedures).
3. National Health Insurance Law (1994) – mandating national healthcare for all citizens, defining the responsibility of medical insurance organizations and of the Ministry of Health vis-à-vis the citizen.
4. National Insurance Law [integrated version] (1995) – establishing the role of the National Insurance Institute (NII), Israel's social security agency that defines, among others, eligibility for partial or full disability compensation.
5. Law on Equal Rights of Persons with Disabilities (1998).
6. Law on Day-Care Rehabilitation Centers (2000) – mandating the establishment of specialized integrative service settings for infants and toddlers with special needs.
7. 7th Amendment to the Special Education Law (2002) – known as the Integration Law – mandating the right to community integration for children with special needs.
8. 43rd Amendment to the National Health Insurance Law (2008) – pertaining to the equal rights of children and adolescents with ASD to receive 3 weekly hours of specific therapies.

In recent years, parent organizations have been advocating for the introduction of a designated Autism Law that will incorporate all the rights of individuals with ASD.

Mandates for Service and Overview of Current Treatments and Centers

Eligibility for health, education, and welfare support and special services for individuals with ASD in Israel is determined based on a multidisciplinary diagnosis. The diagnostic procedure requires: (a) a diagnosis given by a specialized medical doctor (child development specialist, child neurologist, or child psychiatrist) based on *DSM-5* criteria (APA 2013) and (b) a psychological assessment. The psychological assessment procedure includes standardized ASD measures (e.g., ADOS-2, ADI-R, CARS-2), as well as measures of cognitive abilities (e.g., Mullen and Wechsler scales, according to age) and of adaptive functioning levels (e.g., Vineland adaptive behavior scales).

Multiple government ministries share responsibility for community-based service delivery to individuals with ASD, including diagnostic, therapeutic, and psychiatric services delivered via the Ministry of Health; special education services delivered via the Ministry of Education; rehabilitation services delivered via the Ministry of Welfare; and additional benefits delivered primarily via the NII. To be noted, up to this day families continue to face the burden of paying out of pocket for diagnostic, therapeutic, educational, leisure, occupational, or residential services. In particular, they are required to contribute a considerable amount of money to supplement governmental budgets, in order to support integrated community-based services. The services are offered equally to citizens of all religions and ethnic sectors.

Below is a short overview of the services and benefits that pertain to the relevant government ministries.

Ministry of Health

Health services for children with ASD may be delivered directly by Ministry of Health-approved service providers or may be offered by one of the four official national medical insurance service providers (as part of their developmental pediatric services). Children are eligible for diagnostic, therapeutic, and psychiatric services as follows:

- **Diagnostic services.** Early child development centers (operated directly by the Ministry or by medical insurance organizations) are responsible for the diagnostic procedure that establishes children's eligibility for treatment, special education services, and compensation via NII (see below). As reported (Davidovitch et al. 2013), in 2005, the majority of children with ASD in Israel (85%) were diagnosed before the age of 3 years. To this day, there is a great public shortage of available medical and psychological personnel to supply the mandatory ASD diagnostic assessment procedure to children waiting for this service. As a result, the private market is called upon to support the growing need for diagnostic services. It is this fact, in and of itself, that often causes an increase in individual as well as national health expenditures, although the details of this situation on the ground are beyond the scope of the current discussion.
- **Therapeutic services.** In line with the Israeli national healthcare law of 1994, every preschooler diagnosed with ASD is eligible to obtain the multidisciplinary community-based therapeutic basket of 14 hours per week from the Ministry of Health, through approved service providers (as anchored in the Ministry's internal guidelines). This basket allows for the integration of various kinds of treatments for each child, such as speech and language therapy, occupational therapy, physiotherapy, behavior analysis, psychotherapy (including parental guidance and family therapy), and so on. Approved NGOs deliver this integrative service model to preschoolers with ASD in two different community-based special education settings, the first operated by the Ministry

of Welfare and the second by the Ministry of Education, both in conjunction with the Ministry of Health: (1) rehabilitative day-care centers for infants and toddlers with ASD aged 1–3 years and (2) preschools and kindergartens for young children with ASD aged 3–7 years.

Families who elect to place their preschoolers in mainstream educational settings are entitled to receive the aforementioned basket from community-based NGOs' multidisciplinary clinics. Those preschool children who do not yet have access to these services (due to current shortages in available professional resources) are eligible for 3 weekly hours of ASD-related health care via the medical insurance organizations, as described below.

School-aged children with ASD are entitled to 3 weekly hours of basic therapies through medical insurance organizations. These insurance organizations contract public providers either to render these services in public/private medical clinics or to integrate these services within the education system via NGOs (currently provided by the ACR).

The treatments available to individuals with ASD and their families have evolved in Israel over the years, as ASD prevalence has increased (Davidovitch et al. 2013). The past decade in Israel has seen the development of integrative approaches to treatment. These approaches bring together principles of diverse theories and practices to address the wide range of difficulties encountered by persons with ASD. Treatments range from the traditionally widespread psychoanalytically oriented therapy to neuropsychological developmentally based interventions and empirically supported approaches such as applied behavior analysis (ABA); Treatment and Education of Autistic and Communication related handicapped Children (TEACCH); Developmental, Individual Differences, Relationship-Based model (DIR[®]); the Early Start Denver Model (ESDM[®]); cognitive behavioral therapy; and social skills interventions.

- **Psychiatric services.** Mental health clinics provide child psychiatry services, mostly to

children and adolescents with ASD who have comorbidities (e.g., attention deficit-hyperactivity disorder, anxiety disorders, obsessive compulsive disorder, depression) that require pediatric psychiatric consultation. Children older than 6 years with an ASD diagnosis are usually referred to their medical insurance organization's child psychiatry clinic for consultation. Alternatively, some of these patients are referred to one of three tertiary centers specializing in ASD that are available in central Israel: ACR's Bait Echad, ALUT's Autism Center at Assaf Harofe Medical Center, or the Keshet Center for individuals with ASD at Sheba Medical Center. Since 2015, adult individuals with ASD are eligible for psychiatric services under the National Health Insurance Law, which includes psychiatric and mental health services.

As for the availability of hospitalization for individuals younger than 18 with ASD who experience severe behavioral disruptions, only two specialized hospital units are designated for individuals with ASD in the country. Therefore, most individuals with ASD requiring acute inpatient treatment still receive treatment in general child and adolescent psychiatric settings.

Ministry of Education

The Compulsory Education Law (1949) required all children in Israel from age 3 to 17 years to attend school, free of charge, in an educational setting accredited by the Ministry of Education. However, only in 1988 did Israel endorse the law that pertains to special education in a way that assigned therapeutic services to these special students (aged 3–21), based on their specific developmental needs (3.4 weekly hours per student). The amendment from 2002 further stipulated that children who are eligible to receive special education services should have the option of attending school with typically developing peers and should be entitled to designated funding to supply personnel to help children integrate into mainstream education classes (e.g., in-class aides, additional remedial teachers).

Thus, the Israeli Ministry of Education mandates the formation of a special education school

placement committee in each local authority. Based on integrative multidimensional information about each child diagnosed with ASD, the committee prescribes an optimal placement for that child into an integrative education setting or a self-contained special education setting (e.g., an ASD kindergarten). Accordingly, the committee members represent: the local authority (including the committee chairperson and school psychologist), the Ministry of Education (superintendent), developmental pediatricians, social workers, and parents' organizations.

Children between the ages of 3 and 6 years are entitled to placement in a special education kindergarten. Once placed in such a setting, each child's teachers, developmental specialists, and mental health professionals form an integrated problem-oriented pedagogical-therapeutic individualized plan (taking into consideration the needs of the individual family as well). This plan and its implementation are periodically evaluated by the multidisciplinary team and are monitored by the respective Ministries of Education and Health. The collaborative work of these two ministries is anchored in interministerial guidelines from 2015.

Ministry of Welfare

The Ministry of Welfare is responsible for providing rehabilitative treatments as well as leisure activities for individuals with disabilities over the lifespan. To note, all services for individuals with ASD uphold a family perspective and involve family members in their therapeutic programs as well as outreach programs. In addition, the Ministry of Welfare offers partial funding for family support centers nationwide, primarily operated by NGOs (ALUT), which serve thousands of families by providing support, psychoeducational groups, hotlines (in routine and emergency situations), as well as consumer empowerment activities (ALUT).

Specific services are provided by age group. For example, for infants and toddlers (ages 1–3), the Ministry of Welfare, in conjunction with the Ministry of Health, provides early education, a therapeutic basket of medical services, and social rehabilitation, delivered through approved NGOs

and local authorities, who serve as integrative service providers. The Israeli Ministries of Welfare and Health mandate the formation of regional evaluation committees for the placement of infants and toddlers diagnosed with ASD (ages 1–3) to day-care centers throughout the country.

Once a young child is placed in a day-care center, teachers, nutritional specialists, developmental specialists, and mental health professionals form an integrated problem-oriented pedagogical-therapeutic individualized plan (taking into consideration the needs of the individual family as well). This plan and its implementation are periodically evaluated by the multidisciplinary team and are monitored jointly by teams from the Ministries of Welfare and Health.

For school-age children with ASD, various supportive services are anchored in Ministry of Welfare regulations, such as after-school help at home, after-school therapeutic-rehabilitative activities to promote social and communication skills and to advance social integration, and day camps during school vacations.

For adults with ASD, the Ministry of Welfare offers a wide range of community-based opportunities such as training, supervision, and follow-up regarding employment as well as offering occupational facilities; leisure time activities; and protected or independent-living residences. Overall, services for adults with ASD in Israel are provided through the Ministry of Welfare as well as the NII and various NGOs that were created (often by parents) to improve participation and inclusion. Attempts have been made to provide appropriate solutions for different stages of adult development. In typically developing individuals, following secondary education in Israel, adolescents' transition to adulthood usually involves 2–3 years of mandatory military service or civil service. However, most young adults diagnosed with ASD are exempt from military service. To enable individuals with ASD to volunteer for civil or military service, designated support programs have been developed by NGOs, working in collaboration with the Ministry of Welfare and the Ministry of Defense. These programs for civil service (Bat-Ami, Shlomit, Gvanim) and military

service (Hiburim) offer social training and facilitate individually tailored assignment of young adults with ASD to specific military jobs and units. Another program (Roim Rachok – Looking Ahead) capitalizes on the unique strengths of young people with ASD such as attention to detail and systemizing skills, in order to train them socially and professionally for highly needed specialized roles within the military system that rely on such skills. In all these programs, both the individuals with ASD who end up serving in the military as well as their commanders receive supervision and support from professionals. Preliminary results of such programs show participants' improved subjective well-being and quality of life 6 months into the service (Gal et al. 2015).

Additional services to foster independence in young adults with ASD are provided by NGOs and private sector companies (e.g., Avnei Derech, Beit Ekstein, EDNM, Shekel, Shlav, Tigbur), with the support of the Ministry of Welfare. Such programs focus on helping such individuals to move out of their parents' homes either into designated housing for individuals with ASD or into community housing. NGOs also supply vocational training with the support of the Ministry of Welfare and the NII. Specialized vocational training for individuals with ASD is offered by several organizations (e.g., AQA, Beit Issie Shapiro, By the People), capitalizing on the unique skills of individuals with ASD when training them for software quality assurance, computer programming, or information management. Several academic institutions offer pre-academic courses, focusing mostly on independent, social, and executive functioning for this population. One Israeli academic institution, Ariel University, offers its full academic program for high-functioning adults with ASD. During their studies, the students live in dorms with neurotypical students, who support their social inclusion.

Job markets have been open to persons with disabilities since 1998, when legislation mandated occupational and equal opportunities for these individuals. The 2010 amendment to this law mandated a quota of 5% employment of people with disabilities in large public companies, representing the percentage of such individuals

in the general Israeli population. In line with the cultural change that ensued from this law and in order to enhance integration in the labor market, several organizations (e.g., Beit Ekstein, Effie, Shekel) now offer training, opportunities for accessing and mediating jobs, and on-the-job support and guidance to adults with ASD. In addition, based on their functional abilities, adults with ASD may elect to work within specialized community-based employment centers operated by different organizations (e.g., ALUT, Beit Ekstein) throughout the country.

Leisure time and social activities are offered for adults with ASD through NGOs (e.g., Effie, Etgarim, Keshet, Reim, Shekel), some of which also meet age-related needs for intimacy (e.g., dating and sexual education).

Additional National Insurance Benefits

In addition to the aforementioned services, individuals with ASD are entitled to disability benefits under the Israeli National Insurance Law of 1995. Children diagnosed with ASD receive full (100%) NII disability compensation payments until they are 18 years of age. In addition, children from 6 years of age may also be eligible for further NII benefits to allow for appropriate supports if they continue to depend on adult assistance. Adults with ASD over the age of 18 are entitled to further personally tailored support from NII benefits. Other legislature benefiting individuals with ASD and their families relates to tax benefits, extended sick leave for parents to children with ASD, reduced public transportation fees, and more.

Overview of Research Directions

Compared to the vast development of clinical and social services in Israel since the late 1980s that emerged under the aegis of governmental authorities and delivered through medical insurance organizations in collaboration with NGOs, ASD research in Israel has somewhat lagged behind, if measured by output. However, the last decade has seen a steep rise in Israeli ASD research. According to the PubMed free database of

indexed citations and abstracts, research published by active Israeli researchers has increased markedly, from seven papers in 2006 to 40 papers in 2016. Israeli ASD research covers various academic disciplines including biology, neuroscience, clinical medicine, psychology, education, occupational therapy, and more. Researchers from all eight major universities and several colleges as well as university-affiliated hospitals and NGOs are engaged in ASD research, with the most active universities including the Hebrew University of Jerusalem, Bar-Ilan University, University of Haifa, Tel-Aviv University, Ben-Gurion University, and Ariel University. Empirical ASD research is supported by local funding from the Israel Science Foundation, the NII, and the Ministry of Science, as well as by various international foundations and NGOs. Israeli ASD researchers are highly involved in international research collaborations. Key basic research areas of interest to Israeli investigators include, among others, simplex and multiplex ASD genetics, neuroimaging studies, neuroendocrine studies examining the role of specific hormones in ASD (e.g., oxytocin, cortisol, vasopressin), factors associated with high risk for ASD, social cognition, emotion understanding and emotional regulation, sensory characteristics of ASD, the broader autism phenotype as reflected through parental and sibling studies, and parenting characteristics and their effects on children with ASD. Some central applied research foci include school-based social skills training, technology-based interventions for individuals with ASD, and intervention outcome studies in preschoolers and young children. In addition, the first registered clinical trial of cannabis in the ASD population is currently underway at the Shaare Zedek Medical Center in Jerusalem.

Overview of Training

Professionals who work with individuals with ASD – such as occupational therapists, psychologists, special education teachers, psychiatrists, speech and language therapists, and others – receive academic training within their respective

discipline. In addition, specialized training programs in ASD are operated by: (a) each of the relevant ministerial authorities (i.e., Ministries of Health, Education, and Welfare); (b) national professional associations; and (c) the institutions serving the ASD population, which offer teaching, on-the-job training, and supervision in the various disciplines.

Graduate level academic training in ASD studies is offered through the special education master's programs of two universities (Bar-Ilan, Haifa). More focused case-management training is offered by several colleges (David Yellin, Kibbutzim, Levinsky, Oranim). ABA training and certification is available through universities (Tel-Aviv University, Hebrew University) and colleges (Beit Berl, David Yellin, Kibbutzim, Oranim, Wingate). Professional training on standardized ASD diagnostic instruments is offered through the Hebrew University and the ACR (at Bait Echad Centers).

As of yet, the residency program for medical professionals working with individuals with ASD does not include a designated ASD-oriented curriculum. An exception to the rule is a pilot training program established jointly by Geha Mental Health Center and the ACR. In their outpatient clinic residency, all the Center's child psychiatry residents participate in a pilot community outreach program, delivering the mental health basket to young children attending ASD preschools and kindergartens served by the ACR. These residents receive a structured syllabus of teaching and training and obtain supervision and guidance from senior child psychiatrists specializing in the area of ASD.

Social Policy and Current Controversies

Taking into account the rapidly increasing prevalence of ASD and the accumulating evidence attesting to early intervention's optimal effects for ASD trajectories, it is of paramount importance that the Israeli government has assumed responsibility for lifespan public health planning and service delivery for individuals with ASD. However, this governmental commitment remains

geographically limited and significantly declines after the age of 7 years. That is, school-age children, as well as preschoolers living in peripheral areas who lack community-based services, only have access to a limited number of therapeutic hours per week within their medical insurance organization's basket, regardless of their impairment level. Furthermore, adults with ASD are deprived of such therapeutic support and, under the National Health Insurance Law, are only entitled to a general mental health basket resembling any other chronic psychiatric patient.

Against this background, several controversies have arisen in the Israeli public health discourse, focusing on the following questions:

1. To what extent should ASD be considered unique among other developmental disabilities? Should an ASD diagnosis continue to entitle individuals to the current, more privileged service basket, which is richer than that allotted to intellectual impairment and other various kinds of developmental disorders?
2. In view of the increasing prevalence of ASD in Israel, and its accompanying budgetary demands, should diagnostic services be provided by state-monitored specialized centers rather than by private practitioners?
3. Given the limited window of opportunity for early intervention in ASD, should such intervention be governed only by evidence-based practice, which is still rather limited in Israel, or should policy makers call for responsible integrative maintenance of common clinical practice while supporting continual proliferation of ASD research studies? This question pertains not only to the field of autism but also to the general field of psychotherapy for other psychiatric disorders, especially considering the gap between available intervention research data and the clinical scope of application. An evidence-based policy would require the government to undertake a clinically sensitive and scientifically responsible, concerted educational efforts, to educate, train, and monitor the national therapeutic professional community.
4. Considering that ASD is a heterogeneous condition, where diagnosed individuals

demonstrate a range of functioning levels, should the country's limited budget be spent primarily on support for those individuals with more severe disabilities, or rather on rehabilitation of those individuals who have greater potential for adaptive functioning?

5. In view of the diagnostic changes introduced in the *DSM-5*, specifically the exclusion of the pervasive developmental disorder not otherwise specified (PDD-NOS) and the introduction of the new social communication disorder (SCD) as separate from the ASD diagnosis, what is Israel's commitment to individuals bearing the new SCD diagnosis, who may consequently be deprived of their eligibility for the therapeutic ASD basket and thereby their access to community-based ASD services? In the absence of research concerning the new SCD diagnosis and its required treatment modalities, including their costs, should policy changes be implemented to ensure that necessary services and support are delivered to these diagnosed individuals?
6. How should decisions be made regarding the optimal level of inclusion for individuals with ASD in mainstream educational and occupational settings along the lifecycle? What roles should be played by state legislation, professional and community representatives, family members, and the individual herself/himself?

A few words of conclusion are in order. Israel has seen three decades of significant surges in legislature and social policy aiming to promote the rights of persons with ASD throughout the lifecycle, and their families. These rights pertain to available and accessible integrated and specialized services (education, health, and welfare) as well as to work opportunities. Governmental ministries, local authorities, parental organizations, professional NGOs, public and private service centers, and academic institutions have collaborated to bring about these changes in the areas of: service provision, professional education and training, as well as research support. Nonetheless, much remains desired in terms of national planning with regard to the latter two fields.

Considering that ASD is one of the most complex developmental disorders, involving multiple human functional dimensions that require the attention of numerous and diverse systems and fields of care, countries often endorse a range of social policies, spanning from holistic-integrative policies to loosely coordinated field-specific ones. Israel has undertaken a challenging path leaning more toward the holistic-integrative care delivery approach for persons diagnosed with ASD. Integrative complex systems are more vulnerable and difficult to both create and manage. Hence, it remains to be seen as to how the ASD-related care delivery system in Israel will effectively succeed in overcoming its necessarily inherent conceptual, professional, legal, and bureaucratic challenges. Optimal, flexible systemic solutions for these challenges are hard to come by, but once achieved they would serve the best interests of individuals and subgroups with ASD, within their diverse families and communities.

Historical Background

In Italy, interest in early-onset mental disorders dates back to the influential work of Sante De Sanctis (1862–1935). In 1905, he described a condition defined as “dementia praecox pre-puberis” (childhood-onset dementia), which was characterized by early emerging symptoms that we would now recognize as autistic features (Feinstein 2011). In 1898, he founded a scientific organization for the care of children with mental disabilities (*Associazione Romana per la cura medico-pedagogica dei fanciulli anormali*) together with Maria Montessori (1870–1952), a pioneer in child psychology and pedagogy. Maria Montessori’s work focused on the role of education in the promotion of mental health in children with and without mental disability. She developed an educational method (Montessori method), which would eventually spread all over in the world, and came to international prominence as an advocate for education for mentally disabled children.

However, Montessori’s “pedagogical science” approach to childhood mental health lost its relevance after World War II, as the psychiatric culture in Italy became progressively influenced by the psychodynamic perspectives coming from France and the USA (Migoni 1999). Early conceptualization of autism in Italy reflects the prevailing influence of the psychoanalytic orientation, with most professionals considering autism as a psychotic reaction caused by poor parenting. Psychoanalytic psychotherapy for both mother and child was the treatment of choice for children, and care for adults with mental disabilities was limited to long-term institutionalization in psychiatric hospitals. Despite relevant

exceptions (e.g., Zappella 1997; Micheli 1999), the conceptualization of autism as caused by “refrigerator mothers” persisted in Italy both among professionals and in the mainstream culture throughout the 1980s, 1990s, and early 2000s (e.g., Bertolini and Neri 1992; Reda 2003).

In 1978, a law was passed that aimed to end long-term institutionalization of “mentally ill” adults in psychiatric hospitals and established the development of a network of community-based mental health facilities designed to provide short-term targeted treatment. However, adults with autism did not benefit from this legislation as they are classified as “intellectually disabled” as opposed to “mentally ill” under the Italian legislation. Community-based services for adults with ASD, as of today, are still under development.

Starting from the 1990s, parent associations such as ANGSA (*Associazione Nazionale Genitori Soggetti Autistici*) and Autismo Italia were the driving force underlying dissemination of evidence-based knowledge and good practices in service organization through (a) scientific international conferences, (b) training on educational and behavioral strategies (mainly inspired by the TEACCH model), and (c) promoting the translation of scientific literature into Italian. This process was facilitated by the establishment of partnerships with professionals who supported the paradigm shift from psychoanalytical-oriented to evidence-based practice in autism (Caffo et al. 1999; Società Italiana di Neuropsichiatria dell’Infanzia e dell’Adolescenza 2005).

Today, after the publication of the guidelines on autism treatment by the National Institutes of Health (Istituto Superiore di Sanità 2011), the notion of autism as a neurodevelopmental disorder requiring educational intervention is accepted in most clinical, research, and academic settings. However, psychoanalytical approaches to therapy are still implemented in private practice, as indicated by a recent national research report (Censis 2012). Moreover, the implementation of evidence-based practice in school- and community-based settings is still largely affected by unequal availability of resources in different areas of the country.

Legal Issues and Mandate for Services

In Italy, promotion and protection of the rights of persons with Autism Spectrum Disorder (ASD) at the national level are regulated by a legislative framework focused on disability. Article 3 of the Italian Constitution guarantees equal social dignity to all citizens. This principle is reaffirmed in several national laws. The most relevant ordinary laws to persons with ASD are the following:

- L. 104/92, promoting the inclusion and social and functional habilitation of persons with disabilities through intervention, services, and benefits aimed at overcoming exclusion. These include (a) free and compulsory education to all children in the mainstream education system, without any exception or distinction based on the nature or severity of disability, and (b) the legal protection of their civil, political, and patrimonial rights.
- L. 328/00, promoting the implementation of harmonized, essential standards of social services aimed at achieving the inclusion and independence of persons with disabilities across the country. Such standards include the allocation of financial support to independent living as well as the implementation of daily or residential services for persons in need of intense support.
- L. 18/2009, ratifying the United Nations Convention on the Rights of Persons with Disabilities, which defines the principle of equality of persons with disabilities in any aspect of life, without any exception or distinction based on disability, including the need for more intense support.

Nevertheless, the L. 3/2011, which reformed the constitution, established the decentralization of social and health services provision. This law allots to the state government the task of defining the essential levels of social benefits, while rules and policies are regulated by the 20 Italian regions, and the city councils are in charge of the implementation of social services. Some, but not all, Italian regions have established guidelines recommending (a) standardized protocols for

intervention, (b) evidence-based treatments, and (c) “hubs and spokes” organization models of public health services.

Overview of Current Treatments and Centers

Notwithstanding the above legislative framework, policies and services for persons with ASD in Italy show relevant weaknesses. The third research report by the Censis Institute (2012) shows that the access to diagnosis of ASD has improved in the last decade, but delays are still common. The majority of the sample waited 1–3 years for the diagnosis, while 13.5% of the sample, mainly families of adolescents and adults, declared to have waited for more than 3 years. Social services generally fail to meet the support needs for persons with ASD. This lack of adequate support and services indeed has a negative impact on employment of at least one parent (65.9%), mainly on mothers’ employment (62.6% of the sample, compared to 25.5% of fathers) and on parents of those who require more intense support (68.9%, compared to 61.3% of parents of those requiring less intense support).

While almost all young children with ASD receive some treatment, up to 30% of adolescents and adults do not have access to any form of intervention. Approximately half of persons with ASD accessing treatment receive behavioral/educational intervention such as ABA-based programs, TEACCH, and related approaches. Intensity of behavioral/educational intervention is as low as 5 h per week, mostly paid by families. A number of other therapies are provided by the public health system including speech therapy (33% of the sample), “psychomotor therapy” (31%), and psychoanalytic psychotherapy (14%). Over 30% of young children with ASD received only these therapies, with no access to behavioral/educational intervention. A relevant proportion of children (32.2%) receive complementary and alternative medicine therapies, which are in part covered by the public health system despite the lack of evidence to support their efficacy.

Research Directions

In the 2000s, autism has become a growing field of study in Italy, with an increased number of scholars (many of them trained abroad) providing research contributions of international relevance. In particular, the work on the mirror neuron system by the Parma group established one of the most productive research directions in the field in the past decade (Cattaneo et al. 2007; Gallese 2006; Rizzolatti and Sinigaglia 2008). In 2008, the network of research centers “Italian Autism Network” was created with the support of the GlaxoSmithKline Foundation to establish a biologic bank at the University of Verona. In 2015 the Italian Association for Autism Research (Associazione Italiana Ricerca Autismo) was established with the goal to facilitate development and dissemination of scientific research in the field of ASD. Other relevant research directions include genetic and metabolic factors (Lintas et al. 2009; Manzi et al. 2008; Persico and Bourgeron 2006), developmental patterns (Maestro et al. 2005), neurobiology (Keller and Persico 2003), medical and psychiatric comorbidities (Canitano 2007; Mazzone et al. 2012), animal models (Scattoni et al. 2012), treatment effectiveness (Vicari et al. 2012), and psychopharmacology (Masi et al. 2009; Zuddas et al. 2011).

Social Policy and Training

Differences exist in the provision of health and social services that are determined by uneven availability of resources in the Italian territory. Access to school however is guaranteed throughout the country as the school system is regulated by a national legislation, and it is not affected by local availability of resources/budgets. Up to 93.4% of children and adolescents with ASD between age 3 and 19 access mainstream schools. After compulsory school years, only 7% of adults over 21 are enrolled in higher education, and 3% only in vocational training, while 50% are included in day care centers, and 22% stay at home and are not involved in any activity. Finally, 30% do not receive any treatment whatsoever, and 10% only have some form of employment (including sheltered or part-time jobs).

Segregating settings that do not implement targeted educational/habilitation programs represent the only available residential option for 86% of adults with ASD with high support needs. Community-based residential services (small residential communities, group homes) represent a small minority of the available options (4%) and are suitable to persons with mild or light disabilities only (DECLOC Report 2008).

In the past decade, training options for professionals working in autism have progressively increased. These include mainly university masters/postgraduate courses focused on various aspects of ASD, including genetics/biology and clinical management/intervention, and educational approaches.

ITC

► Infant/Toddler Checklist

Item Analysis

Timothy Soto

Clinical Psychology, University of Massachusetts
Boston, Boston, MA, USA

Definition

Item analysis is a process in which responses to test items are examined in order to test the quality of those items. Statistical methods are routinely used to identify any test items that do not belong on the test. Items are removed when they do not show the same kind of patterns of association with other items that is observed among retained test items. In addition, an item analysis will reveal if an item is too easy, too difficult, and/or will show a difference between different types of test-takers. Item analysis can be a useful method in confirming the value of test items for discriminating test-takers with ASD from test-takers without ASD when both groups are administered the same test (Baron-Cohen et al. 2001).

Itinerant Teacher

Karen Meers
Center of Excellence on Autism Spectrum
Disorders, Southern Connecticut State University,
New Haven, CT, USA

Synonyms

Consulting teacher; Early childhood tutor; Inclusion specialist; Peripatetic teacher; Traveling teacher; Visiting teacher

Definition

Itinerant teachers travel to provide services to students with disabilities. Instead of functioning

as traditional classroom teachers, itinerants visit children on their caseloads in a variety of settings including homes, early childhood centers, schools, community-based programs, and hospitals. They provide direct services and supports to children with autism as specified by the goals and objectives in their Individual Education Plans (IEP). Academic skills, communication skills, cognitive development, social development, adaptive skills, motor skills, and behavioral support are some of the categories addressed. They also may provide consultation services to the student's primary teacher or caregiver. Itinerant services denote the location where the services are provided as opposed to the nature of the services themselves (Odom et al. 1999).

Japan and Autism

Hiroshi Kurita

Graduate School of Medicine, The University of Tokyo, Tokyo, Japan

Historical Background

In the field of child psychiatry in Japan, autism has long been one of the most important topics. The first Japanese case of early infantile autism was reported in 1959. Until the end of the 1970s, early infantile autism (Kanner 1943) and “autistische Psychopathie” (autistic psychopathy) (Asperger 1944) were the two major conceptualizations of autism that were employed. Although numerous clinical articles on autistic conditions written in Japanese were published based on these concepts, Japanese child psychiatrists did not have operational diagnostic criteria for mental disorders in place, including such criteria for autistic conditions, until the introduction of the Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III) (American Psychiatric Association [APA] 1980). The subsequent DSM-IV’s (APA 1994) diagnostic criteria have come to be commonly used in research and clinical practice in mental disorders, including pervasive developmental disorders (PDDs) (consisting of five subtypes: autistic disorder, Rett disorder, childhood disintegrative disorder, Asperger’s disorder, and PDD not otherwise specified), although diagnoses

in the International Classification of Diseases, Tenth Revision (ICD-10) (World Health Organization 1993) are used for the national health statistics in Japan. A single category of autism spectrum disorder (ASD) in DSM-5 (APA 2013), which unifies the four DSM-IV PDD subtypes other than Rett disorder, will replace the category of PDDs in research and clinical activities. However, professionals in a non-English-speaking country such as Japan would do better to consider any condition diagnosed as one of the four DSM-IV PDD subtypes to be ASD until a reliable and valid domestic language version of the ASD diagnostic criteria is made available.

Historically, Japanese researchers have made especially pioneering contributions in two areas of research on PDDs. One area is PDD epidemiology. Until the end of the 1980s, the prevalence of infantile autism was reported to be 4–5 per 10,000. Then three Japanese epidemiological studies (Matsuishi et al. 1987; Sugiyama and Abe 1989; Tanoue et al. 1988) independently reported a much higher prevalence of infantile autism, ranging from 13.0 to 15.5 per 10,000. These rates were a harbinger of the high prevalence (62.6–116.1 per 10,000) of PDDs that would later be reported in the UK and the USA (Baird et al. 2006; Bertrand et al. 2001; Chakrabarti and Fombonne 2001). The other area is the phenomenon of regression in autism. Regressive autism was demonstrated to show poorer developmental outcomes in childhood (Kurita 1985) and in adolescence and adulthood

(Kobayashi and Murata 1998) compared with non-regressive autism. On the other hand, the total number of original articles on pathophysiology and etiology of PDDs by Japanese authors was relatively small until the end of the twentieth century. However, it has substantially increased since the beginning of the twenty-first century (e.g., Higashida et al. 2012; Kamio and Toichi 2007; Kato et al. 2008; Nakamura et al. 2010; Sadakata et al. 2012; Suzuki et al. 2013) thanks to the growing interest among researchers coupled with an increasing amount of research funds available from both government ministries and private foundations.

For a long period of time, there were no laws in Japan specifically covering persons with disabilities other than intellectual disabilities (IDs) or physical disabilities. To address this situation, several legislative reforms and amendments to the existing laws have been made over the last 10 years. The “Basic Act for Persons with Disabilities” (Act No. 84 of 1970, amended in 2011) paved the way for persons with disabilities to receive various services equally regardless of the types of disabilities (i.e., physical, intellectual, or mental disabilities [including developmental disabilities]). The “Act for Employment Promotion of Persons with Disabilities” obliged private companies and government offices to have 2 % and 2.3 % of their employees (as amended in 2013), respectively, be persons with disabilities and established systems for supported employment of such persons. The “Act for Supporting Persons with Developmental Disorders” (No. 167 of 2004) was enacted to improve the early detection, remedial treatment, education, employment, and welfare of persons with developmental disorders (DDs) other than IDs not covered by the previous laws (e.g., PDDs, attention-deficit/hyperactivity disorder [AD/HD], and learning disorders) and obliged the 47 prefectures and ordinance-designated cities to establish centers that would support persons with these disorders. The “Act for Supporting the Independence of Persons with Disabilities” (No. 123 of 2005, amended as the “Act of Comprehensive Support for Persons with Disabilities” in 2012) was enacted to

improve the welfare of persons with disabilities so as to enable them to live in the community.

In 2007, special needs education (SNE) to replace the special education system in place prior to that time was implemented in all schools (from kindergarten to high school). SNE aims at providing the relevant education for children with disabilities in order to improve their abilities in dealing with difficulties in everyday lives and their active efforts toward independence and social participation. SNE serves not only children with IDs and children with physical disabilities but also children with DDs other than IDs. In public schools (from elementary to high school), children are educated basically at local government expense regardless of whether they have disabilities or not.

Since PDDs are a part of the DDs and persons with PDDs are covered by the services, systems, and laws for persons with DDs or disabilities, the current knowledge on PDDs/DDs in Japan is described in the following text.

Current Knowledge

Early detection and remedial treatment. The importance of early detection and early intervention in the case of infants with PDDs is well recognized in Japan. All infants have developmental checkups several times in infancy at health centers and pediatric clinics at local government expense, especially at the ages of 1.5 and 3 years. Those checkups are important for the early detection of PDDs. Each local government (city level) has a remedial treatment center for infants with disabilities. A remedial treatment center usually has a clinic which provides child psychiatric/pediatric neurologic examinations and developmental/behavioral evaluations of infants with DDs along with parental guidance. Infants with PDDs detected at infant health checkups are typically enrolled in a remedial treatment group of a remedial treatment center. A remedial treatment group provides infants with PDD activities designed to facilitate their play and interaction with other infants with disabilities in a nursery setting under the guidance of professionals (e.g., nursery

teachers, clinical developmental psychologists, and speech therapists). Parents of infants with PDDs over the age of 3 are encouraged to enroll their children in nursery schools or kindergartens along with participation in remedial treatment groups.

Education. Each local government (city level) has a system in which a panel of experts (e.g., educators and psychologists) advises parents of preschool children with PDDs in selecting a relevant class (an ordinary class with or without the partial provision of SNE or a formal SNE class) of an elementary school or a SNE elementary school for their children. In elementary and junior high school, children with PDDs are educated in ordinary classes with or without the partial provision of SNE, or in SNE classes in ordinary schools, or in SNE schools per se, depending on their levels of intellectual functioning and behavior problems as well as the opinion of the parents. Children with PDDs who graduated from SNE classes in junior high or SNE junior high go to SNE high school. In SNE, teaching methods which have been successfully used abroad, such as the “Applied Behavior Analysis” and “Treatment and Education of Autistic and Related Communication Handicapped Children,” are not systematically incorporated. Instead, besides teaching basic academic and gymnastic skills, the SNE used in classes from elementary to high schools is basically carried out according to the principle of learning through experience, the traditional method of teaching in Japanese special education. Children acquire the skills needed in their everyday lives through the preparation for and accomplishing of organized tasks. For example, if the task is to have a festival, children are taught the steps needed for its effective accomplishment. Then children accomplish each step by learning the necessary skills in cooperation with other children under the guidance of teachers so as to be able to actually carry out the festival. SNE coordinators (teachers having expertise in SNE) help the other teachers deal with children with DDs in various school settings and also advise the parents of the children with DDs. Some high-functioning children with PDDs who graduated from ordinary junior high schools go to SNE high schools, while other such

children, especially those with good intelligence and mild autistic symptoms, are able to attend ordinary high schools. Some of the children with PDDs who graduated from ordinary high schools enter universities. Currently, many universities have a system and staff in place which support students with PDDs.

Employment and work. After graduation from SNE high schools, there are four possible courses or paths for persons with DDs, including PDDs depending on their ability to work. The most able ones work in companies, many of which are branch factories of large corporations that provide employment for persons with disabilities (a monthly income of 100,000 yen [1,000 dollars at a rate of 100 yen to a dollar]). The next most able ones work in “type A” sheltered workshops in preparation for supported employment (a monthly income of 71,513 yen [715.13 dollars]). Persons less able than those working in the type A facilities work in type B sheltered workshops or similar facilities (a monthly income of 7,605–13,742 yen [76.05–137.42 dollars]), and the least able attend facilities designed for the daily lives of persons with disabilities. Persons with high-functioning PDDs who were first diagnosed as having PDDs in late adolescence or adulthood and having had no SNE usually start training for the supported employment program after graduation from high school or university.

Living facilities. There are several types of living facilities in which persons with IDs may live as needed (residential facilities for children with severe IDs, residential facilities for adults with severe IDs, and group homes). Persons with PDDs may enter these facilities if eligible. However, the number of residential facilities for persons with severe IDs will not be increased from the current level, due to the policy of the Japanese government to encourage persons with IDs to live in group homes and not residential facilities. In addition, there are not enough group homes to accept persons in need. Moreover, there are only seven residential facilities for persons with PDDs and severe behavior problems nationwide (five medical facilities capable of providing medical care for patients with behavior problems and two welfare-type facilities).

Pharmacological treatment. Antipsychotics, mainly atypical ones, are commonly used to treat severe behavior problems in persons with PDDs. However, the effects of antipsychotics in such cases have not been demonstrated in randomized controlled trials (RCTs) except for pimozide in Japan. Atypical antipsychotics (e.g., aripiprazole and risperidone) are frequently used to treat severe behavior problems in persons with PDDs based on the positive results obtained in RCTs conducted abroad. The effects of the medications used in the treatment of other comorbid mental disorders (e.g., mood disorders, anxiety disorders, and tic disorders) in persons with PDDs have not been demonstrated in RCTs. Recent progress in the pharmacological treatment of PDDs is the introduction of osmotic-release methylphenidate and atomoxetine to treat comorbid AD/HD symptoms based on research findings that demonstrated such comorbidity.

Financial support. In Japan, there are many types of financial support for persons with disabilities covered by laws for which persons with PDDs are eligible. A person (usually a parent) who is under duty to support a child younger than the age of 20 years with ID of moderate to severe grade (or other disabilities of equivalent severity) is eligible to receive a special child-rearing allowance of 33,570 or 50,400 yen (335.7 or 504 dollars) a month depending on the severity of the disability, provided the annual income of the person or any other person in the same household is not exceeding the norm which rises with increasing number of dependents of the person. An adult from the age of 20 years on with a disability is eligible to receive a pension of 65,541 or 81,925 yen (655.41 or 819.25 dollars) a month depending on the severity of the disability. By the "Act for Supporting the Independence of Persons with Disabilities," persons with disabilities pay none or 10 % of the cost of certain welfare services and medical treatments specified in the act. In the case of 10 % payment, persons with disabilities do not need to pay exceeding the upper limits of the monthly payments (2,500–20,000 yen [25–200 dollars]) which are set according to the household income tax levels.

In addition, 70–90 % of medical treatment expenses other than those specified in this act, such as dental care and the treatment of disease, are paid by one of the public health insurance programs which cover all Japanese citizens. Many local governments have systems in which medical treatment is freely provided to all children younger than 16 years of age.

Organizations of parents and professionals. The Autism Society Japan (ASJ) was established in 1967. The ASJ has conducted various activities such as providing counseling services for persons with PDDs and their family members, holding lectures and workshops, collecting information, and supporting research on PDDs. The Japan League on Developmental Disabilities (JLDD) was established in 1974. The JLDD has conducted various activities, such as supporting persons with developmental disabilities and professionals not only in Japan but also in developing countries, collecting data and information worldwide, and holding national and international academic meetings on developmental disabilities. The Japan DDs Network (JDDNET) was established in 2006. The JDDNET, which is comprised of representatives of associations of parents of children with DDs as well as representatives of associations of concerned professionals, also has conducted diverse activities of supporting persons with DDs and their family members, advancing the understanding of DDs in the society, promoting the welfare of persons with DDs, and carrying out lobbying activities.

Research centers and academic societies. There are three national centers and one national institute which have sections for conducting research on DDs, including PDDs: the National Center of Neurology and Psychiatry, the National Center for Child Health and Development, the National Rehabilitation Center for Persons with Disabilities, and the National Institute of Special Needs Education. There are five major academic societies concerned with research on DDs, including PDDs: the Japanese Academy of Autistic Spectrum, the Japanese Association for the Study of Developmental Disabilities, the Japanese Society for Child and Adolescent Psychiatry, the Japanese Association for Medical and

Psychological Study of Infants, and the Japanese Association of Special Education.

Training professionals. All of the 80 medical schools and the great majority of university departments of education, psychology, and welfare train students in fields related to the DDs, including the PDDs, and also perform research. However, the number of professionals (e.g., physicians, teachers, psychologists, and social workers) having expertise in DDs is quite insufficient to deal with the DD population.

Future Directions

Although the early detection, treatment, education, and welfare provided for persons with DDs including PDDs have shown evident progress over the last 10 years in Japan, many issues remain. First, there is a need to improve the systems for employing persons with DDs. Second, it is essential to provide financial assistance for persons with DDs to enable them to live in the community, because the majority of the adults with DDs get only a pension of 65,541 yen (655.41 dollars) a month, which is by no means adequate to actually sustain them. Third, there is a need to provide an adequate number of group homes for persons with DDs and residential facilities for persons with PDDs and severe behavior problems. Fourth, it is critically important to increase the number of professionals having expertise in DDs. Finally, there is a need to investigate the effects of not only pharmacological treatment of behavior problems and comorbid mental disorders but also methods in remedial treatment and SNE in persons with DDs including PDDs to make them evidence-based practices.

Definition

JASPER: Joint Attention, Symbolic Play, Engagement, and Regulation (JASPER) is a targeted, comprehensive social communication intervention that is included in the broader category of naturalistic developmental behavioral interventions (NDBI; Schreibman et al. 2015).

Goals and Objectives

First developed as a one-on-one intervention, interventionists assess the child to identify developmentally appropriate social communication and play level targets and then select motivating toys that match and advance the child's current skill level. Sessions are densely packed with targeted, systematic instruction designed to engage the child in the development of play routines. These routines provide opportunities to advance children's play skills (both flexibility and complexity of play) and also create the context for communication. The goals of JASPER are to increase: (a) the child's time jointly engaged in a shared activity with a social partner, (b) the diversity, flexibility, and complexity of children's play skills, and (c) spontaneous initiations of both nonverbal and spoken (and/or augmented) language for the purpose of joint attention (socially sharing with others by pointing, showing, or giving objects and/or commenting on the object) and requesting.

Historical Background

The JASPER approach is grounded in children's early development and informed by experimental research examining the similarities and differences in the emergence of core early childhood domains including social engagement with others, social communication skills, and play skills. Research in the 1980s and 1990s demonstrated significant delays in the development of initiations of joint attention skills specific to young children with ASD when compared to children with other developmental disorders and typically developing children (e.g., Mundy et al. 1986; Sigman et al. 1995). Further studies demonstrated differences in the development of play skills (e.g., Ungerer and Sigman 1981) and joint engagement (e.g., Adamson et al. 2009). Yet, these core domains including nonverbal communication and, specifically, initiations of joint attention skills were found to predict language skills for children with autism (e.g., Mundy et al. 1994; Toth et al. 2006) solidifying their critical importance to early development.

and highlighting the need for interventions to support the development of these core skills.

Rationale or Underlying Theory

JASPER follows a developmental progression of skills informed by typical development and research that indicates differences in communicative development unique to children with ASD (e.g., Paparella et al. 2011). The intervention is designed to be individualized. Target skills (goals) based on the developmental hierarchy of each domain are identified for each child to, in essence, meet the child where they are at present, and support their growth based on developmentally appropriate targets. The intervention works within play with objects, a natural learning context for young children. Play routines provide a sensitive and responsive bidirectional context where the actions of the interventionist are informed moment by moment based on the child's signals of engagement, regulation, and communication. The interventionist works to support the child's entry into and maintenance of a joint engaged state. Unlike states where the child is focused entirely on objects to the exclusion of others (object engaged), entirely on a person (person engaged) or not engaged with people or objects (unengaged), time spent jointly engaged has been linked to gains in spoken language (Adamson et al. 2004). Joint engagement allows for a rich learning context where the child may notice the adult's actions on the materials, as well as nonverbal and verbal communication mapped to the materials in front of them. By establishing periods of joint engagement in play, the interventionist sets the foundation to create further opportunities to work on both play and social communication skills.

Treatment Participants

JASPER trials have included toddlers (e.g., Kasari et al. 2010) and preschool age children (e.g., Kasari et al. 2014b). Further, JASPER has been examined with children who have little or no spoken language (referred to as minimally verbal:

Tager-Flusberg and Kasari 2013) who are school-age (e.g., Kasari et al. 2014a). Additional trials are in progress focusing on infants (12–21 months) at risk for autism, children with Down syndrome, and children with tuberous sclerosis complex.

JASPER has been extended to a caregiver-mediated format where parents are coached to use the intervention strategies with their children in both play and home routines (e.g., Kasari et al. 2014b, 2015). Further, JASPER has also been mediated by teachers and paraprofessionals in preschool classroom settings (e.g., Lawton and Kasari 2012; Chang et al. 2016) and early intervention center-based classrooms (Shire et al. 2017).

Treatment Procedures

In JASPER research trials, sessions are 30–60 min in length, typically delivered one on one with a trained clinician and the child, and can occur in clinics, schools, homes, and other community locations. Treatment targets are set during initial assessments. Community trials have included the Short Play and Communication Evaluation (SPACE: Shire et al. 2016a), a brief play-based tool designed to provide community providers with a structured protocol to identify children's mastered skills and set intervention targets for both social communication and play. Based on this information, the interventionist will select play materials that allow for the development of play routines that include the child's mastered play skills and their target play level. Interventionists then work to engage the child in play-based interactions following a manualized protocol. Fidelity is assessed based on video review and includes seven subscales (see Table 1). Both the quality and quantity of the application of the strategies is evaluated. The interventionist is required to individualize the session to first match the child's developmental level and then to provide structure/prompting as required to support the child's engagement and regulation during the session. Progress is noted each session through logs recorded by the interventionist and summative assessment is conducted approximately every 3 months (or 24 sessions).

JASPER, Table 1 JASPER strategy subscales

Subscale	Description of items
Basic strategies to support engagement and regulation	They include foundational interaction strategies such as modeling affect, providing space for the child to communicate, noticing and following in on the child's choices and appropriate actions, and contingent responding. The adult provides appropriate and timely supports to help the child stay regulated and engaged in the play.
Environment	The adult selects developmentally appropriate toy options, provides an appropriate number of toy choices in the environment, sits directly in front of the child, and removes any distractions from the environment.
Balances imitation and modeling	The adult immediately imitates the child's appropriate play actions where the child can see and notice the action. The adult models developmentally appropriate play acts when more structure and support is needed.
Establishing routines	The adult and child create a play routine that has clear steps, where both parties have active roles as play partners. The steps in the routine are at the child's play level and the routine is motivating for the child.
Expanding routines	The adult provides environmental support to help the child add new steps to the play. If the child expands, the adult follows in. If the child does not expand, the adult provides more structure and support to expand the routine.
Programming for joint attention and requesting	The adult notices and responds to the child's initiations of joint attention and requesting skills. The adult also models appropriate skills throughout the interaction and works to provide explicit opportunities for the child to initiate these skills.
Language strategies	The adult imitates and expands the child's appropriate language, and models language at the child's target level.

Coaching caregivers. JASPER intervention has also been tested when delivered by caregivers (e.g., Kasari et al. 2010, 2014b, 2015), and classroom staff including head classroom teachers and teaching assistants/paraprofessionals (e.g., Chang et al. 2016; Shire et al. 2017). To support the adoption of the JASPER intervention strategies by both caregivers and educational staff, trained interventionists provide coaching and feedback while the caregiver/educator practices with the child. Sessions are typically 30 min in length and the content is delivered in progressive segments based on the seven strategy subscales outlined in Table 1. The session typically begins with a visual content handout to help relay the focus of the session (e.g., engagement states, how to balance imitation and modeling). Discussion is kept to only a couple of minutes in order to focus on engaging the child and providing the maximum time for supported practice. Coaches provide supports ranging from modeling strategies for the caregiver/educator (most support), paired interactive practice where both the coach and the caregiver/educator deliver the strategies in

tandem with the child, verbal feedback and tips, and environmental supports (least support). The balance of strategies will depend on the learning style of the adult, the confidence and quality of their implementation, and how many sessions have occurred by that point. Coaches typically begin the first session with the most support (modeling) with the aim to fade the level of support and quickly transfer first the foundational strategies and then the more complex strategies to the caregiver/educator.

Efficacy and Effectiveness Information

Efficacy. The JASPER intervention has been tested in nine randomized controlled trials (RCTs) involving nearly 500 children with ASD over the course of 20 years. JASPER has been tested first as Joint Attention and Symbolic Play modules provided in addition to an intensive ABA center-based program (Kasari et al. 2006, 2008). These modules were then combined together and refined to what was then tested as JASPER.

JASPER trials have compared receipt of JASPER with community treatment as usual controls including agency-based early intervention services, and preschool-/school-based services, and more recently using adaptive intervention designs. Altogether, these trials demonstrate gains in children's time jointly engaged in play activities with others (noticing both the partner and the shared activity), initiations of joint attention (e.g., Kasari et al. 2010, 2014b), language (e.g., Kasari et al. 2008), and play diversity (e.g., Kasari et al. 2010) and play level (e.g., Kasari et al. 2014b).

Caregiver-Mediated. In addition, similar gains have been demonstrated when JASPER is mediated by caregivers (Kasari et al. 2010, 2014b, 2015). During initial trials, caregivers were invited into a clinic setting and received direct coaching to deliver the intervention in comparison to caregivers receiving information but no direct coaching (Kasari et al. 2010, 2015), while in Kasari et al. (2014b), interventionists worked directly with low resource families in their homes contrasted with assignment to a group information intervention. In all three studies, caregivers who received direct JASPER coaching demonstrated gains in their delivery of the intervention strategies, and children showed gains in the primary outcome time jointly engaged. Gains in secondary outcomes include increases in play level (Kasari et al. 2014b, 2015), toddlers demonstrated gains in responding to joint attention (Kasari et al. 2010), and preschoolers demonstrated gains in initiations of joint attention (Kasari et al. 2014b). Caregivers who receive JASPER coaching have also demonstrated greater gains in their responsiveness to their child's communicative bids over information only (e.g., Shire et al. 2016b), and greater strategy adoption by caregivers was found to be associated with children's time jointly engaged (Shire et al. 2015).

Teacher-Mediated. Further, JASPER has been adapted for small group settings and deployed through teachers and paraprofessionals in preschool and early intervention classroom settings (Chang et al. 2016; Lawton and Kasari 2012; Shire et al. 2017). In both cases, children who received JASPER versus preschool or early

intervention as usual demonstrated greater gains in time jointly engaged in play rotations with the classroom staff, gains in initiations of joint attention, gains in language to request and to share, and preschoolers demonstrated gains in time spent in functional play routines (Chang et al. 2016). These gains were demonstrated in a proximal measure of change (during the interactions with the classroom staff) as well as distal measures conducted by research staff (Chang et al. 2016) or center staff unfamiliar to the students and trained to deliver the measure (Shire et al. 2017).

Focus on children who have minimal spoken language. JASPER intervention trials have also specifically focused on supporting the communicative development of children with autism who have few or no spoken words. This group of children is characterized as being *minimally verbal* where children enter the intervention with fewer than 20 functional spontaneous words (Tager-Flusberg and Kasari 2013) as measured through natural language samples. Two trials have been published focusing on this population including one pilot trial with children aged 3–5 years where participants received 30 h a week of treatment as usual ABA therapy alone or the ABA therapy plus JASPER for 30 min twice a week for 12 weeks (Goods et al. 2013) leading to gains in initiations of gestures and less time unengaged for children receiving JASPER. The second trial included children aged 5–8 years in a Sequential Multiple Assignment Randomized Trial (SMART) design where children received a combination of JASPER with a requesting language prompting paradigm (EMT: Enhanced Milieu Teaching; Kaiser et al. 2000). All children received the combined JASPER plus EMT intervention where children were initially randomized to also receive access to a speech-generating device (SGD) in treatment sessions or not. After 12 weeks, the child's individual response (gains in spontaneous communication) were assessed. For those children responding slowly, the intervention was augmented by increasing the number of sessions to three per week or providing access to the SGD (see Kasari et al. 2014a for study design details). Children who received access to the SGD demonstrated quicker gains in spontaneous

communicative utterances in the first 12 weeks (Kasari et al. 2014a), and also demonstrated greater gains in initiations of joint attention (Almirall et al. 2016). Together, these two trials provide evidence for positive gains in spontaneous communication for preverbal preschoolers with autism and minimally verbal school age children with autism. Additional trials building on these findings are currently in the field.

Independent Replications. JASPER has also been examined in independent replications (Kaale et al. 2012, 2014). Focused on supporting preschool teachers, this trial and the 1-year follow-up data show gains in initiations of joint attention and play skills over preschool as usual control.

Outcome Measurement

Key outcomes reported in JASPER trials include three core domains: (a) engagement, (b) social communication skill, and (c) play skills.

Engagement. JASPER prioritizes extending the amount of time that children spend in a joint engaged state. Joint engagement refers to a period of time where the child notices both the interaction partner and the shared activity (Adamson et al. 2009). Children may actively reference the adult with eye contact, initiate discrete joint attention skills, and direct the play in a coordinated joint engaged state or they may indicate their awareness through imitation of the partner's play models and/or language, and actively take turns in the play in a supported joint engaged state (Adamson et al. 2009). Gains in time jointly engaged have been demonstrated proximally, for example, in session with clinician or in classroom rotation with teacher, and in interactions between the caregiver and their child in caregiver-mediated trials (e.g., Kasari et al. 2010). Further, changes in engagement have been found to generalize to interactions with partners who were not taught the intervention strategies. For example, Goods et al. (2013) delivered JASPER by clinicians to a small sample of minimally verbal 3–5-year-olds and found the children spending less time unengaged in classroom observations, while Kaale and colleagues (2010) who focused on

teaching preschool teachers found gains in time jointly engaged in the caregiver–child interactions over control.

Social communication. Social communication encompasses initiations of joint attention, responding to joint attention, initiations of behavior regulations (requesting), and spontaneous communicative utterances (spoken and augmented words for the purpose of requesting or joint attention). Key to JASPER outcomes is the focus on children's spontaneous initiations and the exclusion of adult-prompted response. Social communication is often examined using the Early Social Communication Scales (Mundy et al. 2003) which is a semistructured toy-based measure where children are presented with a standard set of objects including toys, a book, hat, car, etc. designed to capture nonverbal and verbal initiations of joint attention and requesting. In teacher-mediated trials, teachers are provided with support to administer the Short Play and Communication Evaluation (SPACE: Shire et al. 2016) to set developmentally appropriate social communication and play target skills, and to assess progress (Shire et al. 2017). For very young children (e.g., infants and toddlers), gains are expected in developmentally young skills such as responding to joint attention (e.g., Kasari et al. 2010) and initiations of joint attention for older children (e.g., Kasari et al. 2014).

Play skills. JASPER places a unique focus on targeting the development of play diversity and increase in developmental play level. Based on typical development, the intervention follows a hierarchy of play skills (adapted from Ungerer and Sigman 1981; Lifter et al. 1993). Play is assessed both within the interaction of clinicians/teachers/caregivers with the children as well as on semistructured assessments of play delivered by independent evaluators (e.g., Structured Play Assessment: adapted from Ungerer and Sigman 1981). Children receiving JASPER have demonstrated both gains in play diversity measured as the number of different unique types of play acts at a given level (e.g., Kasari et al. 2015, 2006) as well as advancement in the complexity/level of the play (e.g., gains in symbolic play Kasari et al. 2014, 2006).

Follow up. Across the trials, follow-up assessments range from 1 to 6 months post treatment exit. Overall, continued gains at follow up have been demonstrated for engagement and joint attention. Kaale et al. (2014) also published a 1 year follow-up study on children enrolled in their 2012 RCT which demonstrated gains in joint engagement and initiations of joint attention for children in JASPER over the control group. However, no significant differences in language skills were found.

Longer follow-up studies have specifically addressed language outcomes across treatment groups. Children enrolled in Kasari et al. (2006) were assessed 1 year post treatment where children who received targeted joint attention or symbolic play intervention demonstrated gains in language over children in the ABA-only control (Kasari et al. 2008). Further, 5 years post treatment, assignment to joint attention or symbolic play interventions predicted greater expressive language skills at age 8 years (Kasari et al. 2012).

Qualification of Treatment Providers

Providers/clinicians must receive training to deliver JASPER. JASPER training begins with supporting a clinician to work directly with children, and then additional training is provided to coach others (e.g., caregiver mediated JASPER, training other clinicians). Clinicians applying for training should have a background working with children with ASD.

[Job development](#); [Tailoring job skills](#)

Definition

Job carving is a supported employment strategy, designed to provide additional employment opportunities for individuals with autism and other disabilities. Job carving involves creating, modifying, or customizing a community-based job such that it can be successfully performed by an individual with disabilities, while simultaneously meeting the needs of an employer. Job carving typically involves conducting a task analysis of a job by breaking it down into a series of smaller steps. This allows an employer or vocational specialist to identify which parts of a job might be completed by an individual with disabilities. Skills carved out from several jobs can be combined into a new job that is tailored to fit the skills, preferences, and level of supports required

for an individual, and meets the needs of the employer. Ideally, job carving capitalizes on the supports available in the natural environment to maximize independence, while minimizing external supports (e.g., a job coach).

Synonyms

[Employment specialist](#); [Vocational trainer](#)

Definition

Supported employment involves providing systems of supports for individuals with disabilities, so they can participate in competitive employment opportunities in integrated workplace settings. One of the most common methods of providing supports to individuals with autism is

job coaching. Job coaching refers to the systematic training of an individual with disabilities in the workplace, by an experienced trainer. The job coach teaches an individual with a disability how to complete an assigned job to the same standards that all workers are expected to achieve. In addition, the job coach teaches other skills that are required to maintain employment in a community setting, such as interacting appropriately with co-workers, accepting feedback from a supervisor, remaining on-task such that an appropriate amount of work is completed each day, etc. Ultimately, the goal of the job coach is to fade their supports over time, and have the individual maintain productivity and appropriate workplace behavior. Job coaching has allowed individuals with a variety of disabilities, including autism, to successfully maintain employment in a wide variety of workplace settings.

Joint Attention

Kathy Lawton

Special Education and Nisonger Center, The Ohio State University, Columbus, OH, USA

Definition

The developmental process of communication is rapid during the first few months of life. Children initially learn to communicate through gestures before they begin talking (Bates 1976; Bruner 1983). Children first communicate requests or interest in an object through eye contact. By 9–14 months of age, children are able to communicate using a variety of gestures, such as pointing, showing, and giving. These early gestures have different functions. Some serve to request that a person do something (protoimperative or requesting gestures). Others are merely intended to share an event or object with another person (protodeclarative or joint attention gestures).

While both protoimperative and protodeclarative gestures develop within the same time frame, children with autism spectrum disorder (ASD) have specific impairments in the development of protodeclarative or joint attention gestures. Many studies have shown that joint attention gestures are specifically impaired in children with ASD (e.g., Curcio 1978; Loveland and Landry 1986; Mundy et al. 1986). Moreover, research has shown that it is easier for young children with ASD to *respond* to the gestures of others rather than to spontaneously *initiate* joint attention gestures (Mundy et al. 1986). Further, close preliminary examination of the sequence in which joint attention skills emerge has indicated differences in children with ASD compared to typically developing peers matched for expressive language age. For children with ASD, pointing and showing to share develop at a later expressive

language age (ELA beyond 20 months), while these skills emerge for typically developing children prior to 20 months ELA. Further, gaze following is last to develop at over 46 months ELA in children with ASD versus at under 20 months in typically developing children. In contrast, the sequence of emergence of requesting skills in children with ASD is similar to typically developing children, with only a delay in pointing to request (Paparella et al. 2011).

Perhaps even more important, the joint attention impairments that young children with autism exhibit impact later development. Mundy et al. (1990) showed that children who had more developed joint attention gesturing demonstrated better language skills concurrently and over time. Other studies note similar effects of joint attention gestures on expressive language (Bono et al. 2004; Dawson et al. 2004; Mundy et al. 1987). Joint attention may also impact other areas of development, such as theory of mind, emotion regulation, and symbolic play (Adamson and Russell 1999; Morales et al. 2005; Mundy and Hogan 1994; Whalen et al. 2006). Thus, joint attention is a core challenge that serves a pivotal role in the development of social communication competence for children with autism.

Joint attention is a core deficit that should be a target of early intervention programs (Mundy and Crowson 1997; Mundy et al. 2009; National Autism Center 2009). After all, it is commonly believed that the long-term social communication outcomes of children with autism may be best if children participate in early intervention that targets the core deficits of autism (Kasari et al. 2005). While it is unlikely that children with autism will “recover” through any early intervention, targeting core deficits may lead to more optimal pruning in certain areas of the brain (Mundy et al. 1997; Mundy 2016). Thus, if intervention is implemented early while the brain is most plastic, it could trigger profound improvements in key domains that depend upon the core deficit (Bruinsma et al. 2004; Mundy et al. 2009).

Several published interventions report success at improving joint attention. Treatment-induced improvements in joint attention are reported for responding to joint attention (e.g., Whalen and Schreibman 2003) and initiating joint attention

(Kasari et al. 2008) and have been shown to increase over time (Gulsrud et al. 2014). Positive changes are also reported for skills that seem to depend upon the successful emergence of joint attention. These skills include joint engagement (e.g., Kasari et al. 2010), vocalizations (e.g., Jones et al. 2006), eye contact (e.g., Kim et al. 2008), turn-taking (e.g., Schertz and Odom 2007), focusing on faces (e.g., Schertz et al. 2007), play (e.g., Whalen et al. 2006), positive affect (e.g., Whalen et al.), emotion regulation (e.g., Gulsrud et al. 2010), empathetic response (Whalen et al. 2006), and friendship quality (Freeman et al. 2015). Targeted naturalistic developmental behavioral interventions (NDBIs) such as Joint Attention, Symbolic Play, Engagement, and Regulation (JASPER) have demonstrated improvements in IJA when delivered not only by clinic based interventionists but when mediated by parents (e.g., Kasari et al. 2014) or teachers (Chang et al. 2016). When delivered by paraprofessionals in the classroom, a targeted intervention was needed to improve IJA over standard practices alone, such as verbal behavior (Shire et al. 2016). IJA has also been shown to increase when a speech-generating device is combined with intervention, as those who have a SGD for the full JASPER intervention show significant IJA gains beyond those who have JASPER without the SGD (Almirall et al. 2016). Not all interventions targeting joint attention are equal as some have shown to have little effect on joint attention outcomes and responding to joint attention bids (Carter et al. 2011; Rogers et al. 2012).

Short Description or Definition

Joubert syndrome (JS) is a rare neurodevelopmental disorder defined principally by abnormalities of the cerebellum and brain stem (Kroes et al. 2011; Maria et al. 1999; Parisi 2009). In addition to classic JS, a number of syndromes which all exhibit the “molar tooth sign” (MTS) on brain imaging are subsumed under the term Joubert Syndrome and Related Disorders (JSRD) and include COACH syndrome (with colobomas, hepatic fibrosis), Senior-Loken syndrome (with kidney disease), Dekaban-Arima syndrome, Varadi-Papp syndrome, and Malta syndrome.

Categorization

JSRD can be classified into six phenotypic subgroups: pure JS, JS with ocular defect, JS with renal defect, JS with oculorenal defects, JS with hepatic defect, and JS with orofaciodigital defects. The JSRD have been considered autosomal recessive based on recurrence risks around 25% and a 1:1 male to female ratio.

Epidemiology

The prevalence of JSRD is estimated at 1:100,000 in the United States (Parisi and Glass 2007). However, given the wide range of clinical features, this is likely an underestimate.

Natural History, Prognostic Factors, and Outcomes

Many of the clinical features of JS are apparent in infancy (Joubert et al. 1969; Bolthausen and Isler 1977). The prognosis for individuals with JS is variable depending on the extent of the abnormalities of the brain. Global developmental delay is frequent, and often there is a degree of moderate to severe mental retardation; however, some children have a mild form of JS with minimal motor impairment and good mental development. In infancy, prognosis is related to the severity of breathing problems, and afterward, prognosis depends mostly on the extent of renal and hepatic complications.

Clinical Expression and Pathophysiology

The most common clinical features of JSRD include hypotonia, significant intellectual impairment, impaired language development, ataxia, atypical breathing patterns, and oculomotor abnormalities. Irregular breathing patterns may include episodes of “panting” with short bursts of tachypnea followed by a short period of apnea. Individuals with JS frequently display abnormal eye movements with nystagmus,

accompanied by sideways head thrusting and eye blinking. Additional features may include dysmorphic facial features including a broad forehead, arched eyebrows, eyelid ptosis, wide-spaced eyes, and an open mouth due to facial hypotonia and ataxia. Affected children may also have skeletal abnormalities such as cone-shaped epiphyses and polydactyly, pituitary dysfunction, and other central nervous system anomalies.

Though cognitive impairment in JSRD is variable, most children display severe intellectual disabilities with global developmental delays (Farmer et al. 2006; Fennell et al. 1999). In one study, the average age of independent sitting was 19 months and the average age of walking was 4 years for those who developed these skills (Maria et al. 1999). Approximately one in five children also show maladaptive behaviors such as inattention, overactivity, social withdrawal, and atypical behaviors (e.g., self-injury, repetitive behaviors) (Farmer et al. 2006).

Reports of autism and autistic symptoms in JS emerged from clinical cases and small group studies in the early 1990s (Holroyd et al. 1991; Ozonoff et al. 1999). Parents reported their children failed to develop language and displayed autistic-like behaviors including lack of social interest, poor sensory integration, tactile defensiveness, repetitive or stereotyped motor mannerisms, and impaired executive functioning (e.g., perseveration, difficulties in shifting attention). In a study of 11 children with JS, Ozonoff et al. (1999) found that 3 met full DSM-IV criteria for autistic disorder and one qualified for a diagnosis of Pervasive Developmental Disorder – Not Otherwise Specified (4/11 = 36%). The children who did and did not meet autism diagnostic cutoffs showed similar levels of impairment in communication skills and repetitive behaviors, but differed in the number of impairments in social behaviors and total number of DSM-IV criteria met.

Subsequent studies, however, have provided evidence that JS is not a primary cause of classical autism. Takahashi et al. (2005) evaluated 31 JS families and found none of the children met the clinical cutoff for autism. They also compared genetic characteristics of the JS children with

those of children with autism and with Down syndrome (DS). The sib recurrence risk for these disorders was 32% in the JS families, 4% in the autism families, and 0% in DS families. Moreover, JS family histories revealed significantly less autism, alcoholism, cognitive, and language disorders in family members than was found in families ascertained through a child with autism. They concluded that JS and autism are genetically distinct disorders and JS is not a significant cause of the autism behavioral phenotype.

Analysis of oromotor functioning and communication in JS yielded further insight into how children with JS differ from those with ASD (Braddock et al. 2006). On standardized measures, those with JS showed mildly impaired receptive language and severely impaired expressive language, which is the opposite of what is often found in ASD. Also the children with JS demonstrated significant oromotor apraxia affecting the tongue, lip, and velum movements, which is not generally a feature of ASD. An interesting pattern emerged in the study of gesture use. In spite of their severe impairment in motor functioning, the children with JS produced gestures when communicating. Furthermore, the individuals whose speech was more impaired used a higher rate of gestures than those with more intelligible speech, which differs from what is seen in classic autism.

These detailed studies confirmed that JS and related disorders are not a significant cause of the autism phenotype. Nevertheless, comparing ASD and JS provides an excellent example of how complex neurodevelopmental disorders can overlap in their broad symptomatology and even their neuroanatomical findings. Early on, consideration of a possible causal link between JS and ASD was bolstered by the neuroanatomical work of Courchesne et al. (1988) indicating hypoplasia of the posterior cerebellar vermis in ASD and the recognition of frequent anatomic defects in cerebellar structure in ASD (Miles and Hillman 2000). Clarification of JS as a ciliopathy, however, showed that the similarities were superficial and not causal.

Previous research on the pleiotropic effects of major disruptors of brain development, such as in the ciliopathies, has shown that

neurodevelopmental disorders with disparate causes will often exhibit some symptom overlap. And, as suggested by Alvarez Retuerto et al. (2008), future studies may show that individuals heterozygous for one of the ciliary mutations may have an increased ASD susceptibility. Dissecting these interrelationships depends on careful phenotypic analyses and, as in the case of JS, is ultimately solved by identifying the underlying genetic etiologies of each. Above all, clinicians must be prudent when counseling families on either prognosis or recurrence unless the diagnosis is clear, and preferably the underlying genetic defect is proven.

Evaluation and Differential Diagnosis

The “molar tooth” sign on brain MRI is pathognomonic (Maria et al. 1997). Named because it resembles a cross section through a molar tooth, this brain abnormality is caused by cerebellar vermis hypoplasia, deepened interpeduncular fossa and thick, elongated cerebellar peduncles (see Fig. 1). Because of the multisystemic effects of JS, evaluation must include ophthalmologic, renal, hepatic, dysmorphology, and neurologic assessments (Parisi and Glass 2007).

Recent discovery of genes that cause JSRD has clarified the clinical heterogeneity noted in the syndromes defined by the molar tooth sign (see Parisi 2009 and Brancati et al. 2010, for recent reviews). Mutations in ten genes which cause impairments in the primary ciliary apparatus (*INPP5E* at 9q34.3, *TMEM216* at 11p12-q13.3, *AHI1* at 6q23.3, *NPHP1* at 2q13, *CEP290* at 12q21.32, *TMEM67/MKS3* at 8q21.1, *RPGRIP1L* at 16q12.2, *ARL13B* at 3q11.1, *CC2D2A* at 4p15.32, *OFDI* at Xp22.2) account for about half of causative mutations in JSRD (OMIM # 613037, 613,277, 608,894, 607,100, 610,142, 609,884, 610,937, 608,922, 612,013, 300,170). Each of these genes encodes for proteins of the primary cilium, making JS and related disorders members of the group of “ciliopathies.” Nine are autosomal recessive, one is X-linked recessive, and testing is clinically available. Primary cilia play key roles in the development and function in the brain, kidney, liver, and retinal cells

Joubert Syndrome, Fig. 1 Molar tooth sign. (Courtesy of Dr. Bernard Maria and the Joubert Foundation)

regulating tissue differentiation, establishment of body axis, growth, and intercellular signaling processes (see Lee and Gleeson 2011 for review of the role of cilia in the nervous system). Several of these ciliary proteins have been implicated in the modulation of signaling pathways, such as sonic hedgehog (Shh), Wingless (Wnt), and phosphatidylinositol (Bielas et al. 2009; Valente et al. 2010; Lancaster et al. 2009). Most cells in the brain including neurons, glial cells/astrocytes, and ependymal cells have primary cilia. Involvement of multiple genes that influence ciliary movement helps explain the clinical variability and heterogeneity described in JSRD. It has been shown that the same ciliary gene may cause many different phenotypes (allelic heterogeneity) and several different genes may be associated with the same clinical features (locus heterogeneity). Moreover, there is emerging evidence for oligogenic inheritance, where full penetrance of a phenotype requires mutations in more than one of the cilia genes.

Treatment

Presently, there is no cure for JS and treatment is symptomatic. Children with JS with abnormal breathing should be monitored; therapy includes stimulatory medications or mechanical support. Management of ophthalmologic problems may include surgery, corrective lenses, or therapy. Interventions for hypotonia and cognitive impairment may include early intervention programs for occupational, physical, and educational support. Annual screening is recommended for some of the complications associated with JS, such as liver, retinal, or kidney involvement that may become progressive over time. Individuals with JS also typically require behavioral and rehabilitative therapies and special education services to progress toward individualized goals in learning, communication, motor skills, adaptive behaviors, and socioemotional functioning. Finally, families may benefit from activities that support coping, including parent-to-parent mentoring (e.g., through the Joubert Syndrome Foundation), training in behavioral management strategies, assistance with resource identification, and effective care coordination.

Kanner, Leo

Adam Feinstein
Autism Cymru and Looking Up, London, UK

Major Appointments (Institution, Location, Dates)

Appointed Assistant Physician at the State Hospital in Yankton County, South Dakota, in 1924

Selected by Adolf Meyer and Edward Park in 1930 to develop the first child psychiatry service in a pediatric hospital at Johns Hopkins Hospital, Baltimore

Appointed Associate Professor of Psychiatry at Johns Hopkins in 1933

Retired in 1959 and replaced as Chief of Child Psychiatry by Leon Eisenberg

Landmark Clinical, Scientific, and Professional Contributions

Dr. Leo Kanner's 1935 book, *Child Psychiatry*, won him international acclaim, but it was his 1943

paper, *Autistic disturbances of affective contact*, with its fine detailed clinical descriptions on what he called "early infantile autism" – which is still referenced by autism professionals around the world to this day, despite a number of deficiencies (in particular, Kanner's startling insistence that the 11 children in his 1943 study had "normal cognitive potentiality"). Kanner considered five features to be diagnostic: a profound lack of affective contact with other people; an anxiously obsessive desire for the preservation of sameness in the child's routines and environment; a fascination with objects mutism or a kind of language that does not seem intended for inter-personal communication; good cognitive potential shown in feats of memory or skills on performance tests; and onset of the condition from birth or before 30 months. For Kanner, the children had never been engaged with the social world. Kanner's 1943 paper certainly represented a seminal landmark in the identification and understanding of autistic behaviour. Nevertheless, Hans Asperger – whom Kanner never cited – had been working in the field from the early-1930s and published a paper on what he called "autistic psychopathy" in 1938. Apart from Kanner's puzzling reference to his patients' normal cognitive potentiality, he also did not seriously consider an organic etiology until Stella Chess's congenital rubella paper in 1971 – despite the fact that two of the 11 children in his 1943 study had epilepsy.

Short Biography

Leo Kanner (pronounced “Konner”) was born Chatskel Leib Kanner in the small Austrian village of Klekotow (called Klelotiw today) on June 13, 1894. As a young boy, he moved to Berlin in 1906 to live with his uncle. He initially wanted to be a writer – even while a medical student at the school of medicine at the Friedrich-Wilhelm University in Berlin – but no one would publish his poems. At the outbreak of the First World War, Kanner was recruited into the medical service of the Imperial and Royal Army of Austria and Hungary. In 1920, he became an assistant physician at the Charité Hospital in Berlin, working in the field of cardiology. He left Germany for the United States in January 1924 with his wife and young daughter. His first US post was that of assistant physician at the State Hospital in Yankton, South Dakota, publishing papers on general paralysis and syphilis. His first book, *Folklore of the Teeth*, was published in 1924. He joined the Henry Phipps Psychiatric Clinic at Johns Hopkins University in Baltimore in October 1928, working under the Swiss psychiatrist Adolf Meyer. Kanner won international renown with the publication of his book, *Child Psychiatry*, in 1935. His landmark paper, *Autistic Disturbances of Affective Contact*, was published in 1943. Although he retired as Chief of Child Psychiatry at Johns Hopkins in 1959 to be replaced by Leon Eisenberg, Kanner continued to publish important papers on autism until 1973. He and his wife, June Lewin, opened their home to many of the European refugees from the Nazis whom he had personally helped to reach American soil safely. Kanner died in Sykesville, Maryland, on April 3, 1981.

Karyotype

Ellen J. Hoffman

Albert J. Solnit Integrated Training Program, Yale Child Study Center, Program on Neurogenetics, Yale School of Medicine, New Haven, CT, USA

Definition

A karyotype is an organized picture of an individual's entire set of chromosomes: 22 pairs of autosomes (nonsex chromosomes) and 1 pair of sex chromosomes (XX or XY). Karyotypes are used

in cytogenetics to identify abnormalities in the number or gross structure of an individual's chromosomes (Jorde et al. 2010). The picture that makes up the karyotype is taken during metaphase because the chromosomes are condensed and more easily visualized during this stage of mitosis. The chromosomes are stained with Giemsa stain, which produces a characteristic set of bands (G bands), and aids in the identification of alterations in chromosome structure, such as large deletions, duplications, or inversions (Jorde et al. 2010).

Recent guidelines recommend obtaining a karyotype as well as testing for fragile X syndrome in the evaluation of all individuals with autism spectrum disorders (ASD) (Lintas and Persico 2009; Schaefer and Mendelsohn 2008). The rationale for this recommendation is that there is evidence that approximately 2–5% of individuals with ASD have gross abnormalities in chromosome structure, which may be identified by karyotype (Reddy 2005; Schaefer and Mendelsohn 2008; Shen et al. 2010). Although identifying a chromosomal abnormality in a child with ASD in most cases does not alter the treatment plan, this knowledge is important for genetic counseling of families with regard to recurrence risk and may identify medical risks associated with certain chromosome abnormalities (Schaefer and Mendelsohn 2008).

At the same time, the information obtained from a karyotype is limited, because submicroscopic deletions or duplications, which accumulating evidence indicates are often associated with ASDs, are not detectable by karyotyping (Shen et al. 2010). Moreover, recent studies have found that a clinical microarray (CMA), or array comparative genomic hybridization, which can detect such submicroscopic variants, would increase the diagnostic yield in ASD to 10%, which does not include the 5% detection rate for karyotyping alone (Schaefer and Mendelsohn 2008). These findings have led to the consideration of CMA as part of the initial diagnostic evaluation of ASD (Shen et al. 2010). Although the findings from a karyotype or CMA do not dictate a specific therapeutic approach at this time, current research in the genetics of ASD aims to utilize knowledge

of the genes that are disrupted by alterations in the structure of chromosomes as an avenue to identify common biological pathways and novel therapeutic interventions.

KABC-II

Description

The KABC-II (Kaufman and Kaufman 2004a) is a standardized cognitive assessment suitable for children aged 3–18. It provides age-based standardized scores, age equivalents, and percentile

ranks. The time for administration varies from an estimated 25–70 min, depending on the age of the child, subscales administered, and individual differences of the participants. Overall, this intelligence assessment includes 18 core and supplemental subtests, which are grouped into four or five distinct scales, depending on the child's age and cognitive model selected. The test is based upon two theoretical models, including Luria's (1970) neuropsychological framework and the Cattell-Horn-Carroll hierarchically organized model (CHC; Carroll 1997).

The user can select the theoretical framework most suitable for the particular child being evaluated; the CHC framework is suggested for typically developing children from a mainstream language and cultural background, whereas the Luria framework tends to be more suited for participants with atypical cognitive functioning, such as Autism Spectrum Disorder (ASD) and other language or hearing impairment, as it excludes verbal ability. The same subtests are administered and the user can interpret results based upon either model. The test itself uses colored pictures and manipulatives to facilitate interest and promote ease of use with young or vulnerable children.

The CHC model is the newer approach, added to this revised edition of the assessment. It consists of Short-Term Memory (Gsm), Visual Processing (Gv), Learning Ability (Gl), Fluid Reasoning (Gf), and Crystallized Ability (Gc) subscales. The overall global score is termed the Fluid-Crystallized Index (FCI) and is developed from these Broad Ability measures.

The Luria model uses four of the five identical subscales to contribute to a global score (Mental Processing Index, MPI), but they are instead referred to as Sequential Processing (Gsm in CHC), Simultaneous Processing (Gv in CHC), Learning (Gl in CHC), and Planning (Gf in CHC). The Gc scale of the CHC model is termed Knowledge Scale using the Luria interpretation but does not contribute to the global score. The key difference between the two global scores is that the Luria approach (MPI) excludes acquired knowledge, whereas the CHC (FCI) includes measures of acquired knowledge and distinguishes between fluid and crystallized

intelligence. Only one of these global measures is calculated for each individual participant.

Each subscale consists of several further subtests. The Simultaneous Scale (Gv) includes Triangles, Face Recognition, Pattern Reasoning (ages 5–6), Block Counting, Story Completion (ages 5–6), Conceptual Thinking, Rover, and Gestalt Closure. The Sequential Scale (Gsm) tests Word Order, Number Recall, and Hand Movements. The Planning (Gf) scale focuses on Pattern Reasoning and Story Completion, only for children aged 7–18. The Learning Scale (Gl) includes Atlantis, Atlantis Delayed, Rebus, and Rebus Delayed. Finally, the Knowledge/Gc scale includes Riddles, Expressive Vocabulary, and Verbal Knowledge but is computed only for the CHC interpretation.

Subtest scores have a mean of 10 and a standard deviation of 3, and both global scores (FCI and MPI) have a mean Scale Index of 100 with a standard deviation of 15, keeping in line with the majority of cognitive instruments. Descriptive categories are also provided (Above Average, Average, Below Average, etc.). Scoring is either done by hand or with a separately purchased computerized system (ASSIST) which provides a score summary, scale profile, achievement comparison, and diagnostic information.

In addition to the FCI and MPI, the KABC-II includes a Nonverbal Scale that can be administered and responded to motorically. The KABC-II includes both Core and Expanded batteries, the latter of which do not contribute to standardized subscores but may be used clinically to follow up hypotheses and provide a comparison of delayed recall of learning to initial learning measures. The authors note that in order to provide a complete picture of a child's abilities across a range of domains, this test should be supplemented with other well-established measures.

Historical Background

The K-ABC was initially developed in 1983 by Alan S. Kaufman and Nadeen L. Kaufman, and was one of the first standardized measures of intelligence tests founded on real theories of cognitive processing. It was based on the Luria (1970)

model of sequential and simultaneous mental processing (see also Das et al. 1979) combined with left brain-right brain research on cerebral specialization (Sperry 1968). According to Luria, the brain is characterized by three functional systems, or “Blocks,” which promote arousal and attention (Block 1), analysis, coding, and storage of information (Block 2), and executive functioning and planning (Block 3). The integration of these functional systems is thought to support overall behavior; thus the K-ABC was created to assess the mental systems which arise from the integration of these blocks.

The initial edition evaluated children aged 2.5–12.5 years, and was touted as a culturally fair instrument, arguably unlike Binet and Weschler scales. This was due to the narrowing of the gap between K-ABC scores of White children and minority groups such as African American and Native American children; traditional cognitive assessments tended to show a prominent difference between such subgroups, but the K-ABC reduced this gap by roughly half a standard deviation. The novelty and importance of this test in particular also stemmed from its goal in evaluating underlying mental processes rather than the products of task performance. Although many supporters of the test praised its theoretical basis and clinical validity, other clinicians questioned whether the test was as internally or externally valid as claimed. In fact, a special issue of the *Journal of Special Education* in 1984 was devoted to these contrasting viewpoints.

Taking these issues into consideration, the authors decided to revise the test in order to strengthen theoretical foundations and enhance clinical use and validity in a wider range of participants, including preschoolers (Lichtenberger and Kaufman 2007). The new edition (KABC-II) has expanded to test an older age range of wider ability levels and cultural backgrounds and was released in 2004. It is theoretically based not only upon Luria’s model, but also the Cattell-Horn-Carroll hierarchically organized model (CHC; Carroll 1997). The CHC is a data-driven theory that merges two separate, but related, models which both focus upon the spectrum of broad human cognitive abilities. Raymond Cattell’s (1941) original two-pronged Gf-Gc theory,

which was subsequently revised by Horn (1965), was combined with John Carroll’s (1993) factor analysis on cognitive abilities. This resulted in a combined theory founded on decades of research on the concept of “g” (a general factor of intelligence) and broad cognitive abilities.

The KABC-II thus remains an intelligence test heavily grounded in empirical data, which sets it apart from other similar instruments. Other benefits from this revised edition include cultural fairness, as the materials contain scarce cultural content in order to equate individuals from diverse backgrounds. The test creators suggest that the KABC-II provides a veridical picture of a child’s abilities, as language difficulties and cultural differences do not contribute to the overall assessment.

Psychometric Data

The KABC-II Test Manual provides a detailed analysis of test development, factor structure, and test interpretation (Kaufman and Kaufman 2004a). The KABC-II has been normed on 3,025 participants ranging from age 3–18, representing a range of ethnicity, parental education, geographical location, and special education or gifted placement (see manual). The sample was stratified to reflect US population samples based upon 2001 Census data, thus providing an accurate distribution of children across the USA. The test manual provides extensive details on the validation study, in addition to reliability and consistency measures. The KABC-II was co-normed with the Kaufman Test of Educational Achievement, Comprehensive Form, Second Edition (KTEA-II; Kaufman and Kaufman 2004b).

Clinical validity has been established with several atypical groups, including children with ASD, ADHD, Learning Disabilities, and Gifted children. The KABC-II has good reliability for core and supplementary subtests, and recent research also reports good construct validity (Reynolds et al. 2007).

The median internal consistency reliability coefficient for ages 3–6 is 0.85, with a 0.87 coefficient for ages 7–18. Test-retest reliability coefficients of the global scales range from mid-0.80s to

mid-0.90s for the FCI and MPI, with retest stability increasing with age. Correlation analysis reveals that scale indexes maintain an appropriate amount of independence and thus tap into different processes, but also stem from a unitary underlying construct.

Clinical Uses

The KABC-II has been used with hearing impaired, learning disabled, and crosscultural populations. Although the test is administered in English, credit is given for answers presented in other languages (e.g., Spanish).

With respect to ASD, this test is ideal for non-verbal participants or those with limited language processing ability, due to option of delivering nonverbal test instructions in the form of modeling/pantomime and accepting motoric rather than verbal responses. This newer edition is thus arguably better suited (Bain and Gray 2008) for detecting a profile of processing strengths and weaknesses, which is essential for capturing the individual differences on the autistic spectrum. The information gleaned from the KABC-II assessment can help facilitate clinical, educational, and intervention planning.

This test may be administered by a variety of qualified users including Registered Psychologists (USA) and Chartered Psychologists recognized by the Health Professions Council (UK). Professionals with certification of in-house training by a Chartered Clinical Psychologist within certain government services are also permitted to use this test.

KBIT-2

Description

The Kaufman Brief Intelligence Test, Second Edition (KBIT-2), is a reliable, valid, and norms-

based brief assessment of intelligence for individuals aged 4–90 years. The KBIT-2 provides a valid and reliable way of assessing both verbal and nonverbal intelligence in approximately 20 min. The KBIT is based on the Cattell-Horn-Carroll (CHC) hierarchical model of general intelligence, in which a number of Broad Abilities are broken down into Narrow Abilities. In addition to an overall measure of cognitive functioning, the KBIT assesses two Broad cognitive abilities: Crystallized (verbal) knowledge and Fluid (nonverbal) knowledge. A strength of the KBIT is that it can be quickly and easily administered to individuals across a very wide chronological age range. However, because of its brevity, it does not provide as thorough an assessment of intelligence as other more in-depth assessments, such as the authors' own Kaufman Assessment Battery for Children (KABC), which takes 25–55 min to administer. Given the limited number of scales on the KBIT-2 it is not possible to profile an individual's profile or pattern of relative strengths and weaknesses.

The KBIT-2 consists of three subtests, which are organized into two scales; all three subtests draw from the longer-form Kaufman Assessment Battery for Children, second edition (KABC).

The Crystallized (Verbal) Scale includes: (1) a Verbal Knowledge subtest, which is designed to assess an individual's general knowledge and receptive language skills, and (2) Riddles, which is designed to assess both receptive and expressive language.

The Fluid (Nonverbal) Scale consists of a Matrices subtest, which is designed to assess an individual's nonverbal, abstract reasoning abilities.

All of the materials, or stimuli, that are presented to the examinee are in color.

The Verbal Knowledge subtest, containing 60 items, is a receptive measure of the child's store of English-language vocabulary and of general information.

The subtest is composed of a series of multiple choice questions that require respondents to point to or say the letter of the correct response.

There are no teaching items; instructions are provided in English only.

The Riddles subtest is composed of 48 items, in which a series of verbal riddles are presented and the examinee is asked to either point to the picture or say the word that provides the answer to the riddle. This test measures an individual's verbal comprehension, verbal reasoning, and word retrieval.

The Matrices subtest is composed of 46 items including several types of visual stimuli (e.g., people and objects as well as designs and symbols) and requires individuals to understand relationships between the stimuli. All of these items are multiple choice, requiring individuals to point to or say the letter corresponding to the correct response. Sample and teaching items are provided, as are Spanish language instructions.

All items are administered from a testing easel, and correct responses and examples of typical responses that need to be queried are printed on the easel facing the examiner.

A major limitation of the KBIT-2 Crystallized (verbal) scale is that it must be administered in English. However, if an examinee provides a correct response in another language they are given credit, and correct Spanish language responses are included on the record form for the Riddles subtest.

Historical Background

The KBIT-2 is a revision of the original version of the Kaufman Brief Intelligence Test. The original KBIT was published in 1990 and also included both verbal and nonverbal intelligence measures, although the verbal subtests were revised in the second edition; the first edition included only one subtest, Vocabulary, as opposed to the KBIT-2's Verbal Knowledge and Riddles subtests.

Psychometric Data

The KBIT-2 generates three standard scores, with means of 100 and standard deviations of 15: an overall measure of intelligence (the KBIT IQ composite), as well as a Crystallized and a Fluid standard score. The examiner records scores for

each tasks and converts the subtests to standard scores using the manual, which also provides tables for comparing individuals' performance on the different scales to determine whether the difference is significant. The KBIT-2 provides age-based norms that were based on a national standardization sample selected to match the US census data. Standard scores can range from 40 to 160 for most ages, with the exception of the very low and high ends of the age range.

Standardization occurred between May 2002 and May 2003 across 34 states and the District of Columbia, and the sample included 2120 children and adults. Random sampling methods were used to select individuals from a larger pool of potential examinees, matching the US Census data.

The KBIT-2 has demonstrated strong reliability and validity, comparable to the Wechsler Intelligence Scales for Children – fourth edition (WISC-IV). Split-half reliability coefficients are high, in the range of .80 to mid-.90s. Mean split-half reliability scores across all age groups were .91 for the Verbal Scale and .93 for the Composite IQ. The only statistically significant sex difference observed was for children of ages 7–12 years, favoring females for 2.4 points. Test-retest reliability coefficients ranged from .88 to .93. Across ages, peak performances for Verbal Knowledge and Riddles were in the 26–35-year-old range, with decreases observed at higher ages. The measure also demonstrates concurrent validity with other assessments of cognitive functioning, including the Wechsler Abbreviated Scale of Intelligence (WASI), where correlations range from .81 to .90 for the composite scores.

While the manual includes data from seven groups of participants with special needs, including individuals with intellectual disability, no data from individuals with Autism Spectrum Disorders is presented.

The KBIT test was normed as a brief test, a strength relative to the short forms of other intelligence assessments that were extrapolated from longer, more comprehensive tests. The KBIT-2 was also co-normed with the Kaufman Test of Educational Achievement – Brief Form for ages 26–90,

which can provide a brief assessment of educational achievement concurrent with the KBIT.

Clinical Uses

Given the brevity of the assessment, the KBIT is a flexible and user-friendly test. Its primary use is to obtain a quick estimate of the intellectual ability of children and adults. However, given its brief nature, it can also be used as a screener to identify children who may require a more comprehensive evaluation. It is relatively simple to administer and does not require a manual. The ease of assessment lends the KBIT to brief administrations, including reevaluations, across a variety of contexts (e.g., clinic, school).

However, also because it is brief, intelligence scores should be held tentatively and should *not* be the basis of major clinical decisions about diagnosis or placement; such decisions require more comprehensive assessments of an individual's cognitive testing. Moreover, although KBIT scores correlate with overall intelligence scores, because of the brevity of the test, it does not assess the full spectrum of cognitive functioning (e.g., there are no rapid responses required on the KBIT).

Because of its brevity and ease of administration, the KBIT and KBIT-2 have been used often as a brief measure of cognitive functioning in research studies of individuals with ASD frequently as a way of differentiating “high functioning” individuals with autism (defined as a verbal or composite IQ score on the KBIT-2 greater than 70). However, extensive research on the use of this measure among individuals on the spectrum has not been conducted. A potential drawback of the KBIT as a measure is its reliance on expressive language on the Riddles subtest.

Kazakhstan and Autism

Janyl Mukashova
Autism Program, Bulat Utemuratov Foundation,
Almaty, Kazakhstan

Historical Background

Autism is a new diagnostic concept for Kazakhstan. There is no accurate data on the number of autistic children in Kazakhstan. In accordance with data of the State Republican Psychological-Medical-Pedagogical Committee as of 2017, the approximate number of autistic children in Kazakhstan is around 3000. In 2003 the number of identified autistic children was 77.

Kazakhstan accepted International Classification of Disease (ICD) in January 2010, so medical services for autistic children in Kazakhstan are based on ICD classification. The main principles of medical services in Kazakhstan are stated in the Code “Health and the health system” of the Republic of Kazakhstan. By the Code, autism is

under category of psychiatric disorder, so child psychiatrists are the only diagnosticians. Parents of autistic children have many fears including lack of access to any educational system, including specialized schools. In case of severe behavioral problems, the child would be put into a child psychiatric dispensary.

At present there is no program of autism screening and diagnosis by state. Extremely limited organizations use evidence-based screening and diagnosis methods for treatment purposes.

By the Code, autistic children in Kazakhstan are eligible for state social allowance till 18 years old. They are considered as disabled children and usually put into specialized state schools, for example, specialized schools for children with speech/hearing/mental/psychological/problems, etc. At present there is no public school inclusion of autistic children into educational system of Kazakhstan.

Until 2017 there was no official state recognition of autism. Limited number of NGOs and foundations started autism support activities and promoted Autism Roadmap, which is finally accepted by the Ministry of Health of the Republic of Kazakhstan. This is the first official sign of autism recognition in Kazakhstan.

Limited numbers of NGOs started autism support activities in 2014 organizing public awareness activities, press conferences, and informational workshops for parents, providing sport activities for autistic children, etc. Some of them promote inclusive education. The total number of NGOs and foundations supporting autistic children is about ten. Only one specialized state department within the National Child Rehabilitation Center serves autistic children in Kazakhstan.

Among NGOs and foundations, four “Asyl Miras” autism centers established by Bulat Utemuratov Foundation in 2015 are the only organizations which use ASD screening and diagnosis methods such as M-Chat-R and ADOS-2; provide learning and language programs using ABA therapy and JASPER program of University of California in LA, USA; and collect and analyze intervention data.

There are no state programs to support autistic children, except one small pilot project of the Ministry of Education, which allows integration of very limited number of ASD children into state education system in Astana city. The project is piloted in five state schools in Astana city.

There is a hope that if accepted in 2017, Kazakhstan Autism Roadmap in 2017 will accelerate autism support activities and promote destigmatization in Kazakhstan.

Legal Issues, Mandates for Service

In accordance with article #119 of the Code “Health and the health system” of the Republic of Kazakhstan, diagnosing of psychiatric disorders (diseases) is made by a psychiatrist in the following classification: childhood autism, atypical autism, Rett’s syndrome, childhood disintegrative disorder, overactive disorder associated with mental retardation and stereotyped movements, and Asperger’s syndrome. The term autism spectrum disorder (ASD) is used only by NGOs and foundations serving autistic children. As noted previously only child psychiatrists make a diagnosis, and children with autism have eligibility for state social allowance until 18 years of age.

There is a lack of field specialists, who would provide interventions. Most of ASD children support activities or programs run by limited number of NGOs established by parents of ASD children and by few foundations.

Overview of Current Treatments and Centers

The Psychoneurological Department of the National Child Rehabilitation Center (the only one-state institution) provides services to autistic children in the capital Astana. In 2016 the Department served 122 autistic children. The Department uses M-Chat and ADOS and provides services: psychologist, speech therapist, nutrition, sensory integration, and music therapy. The major service provider in Kazakhstan is Bulat Utemuratov Foundation. The Foundation

established four “Asyl Miras” autism centers in Kazakhstan to support autistic children and their parents. Autism centers implement “Autism. World is One for All” program to support 0–15-year-old, autistic children in four major cities in Kazakhstan (Astana, Almaty, Kyzylorda, Ust-Kamenogorsk). As of September 2017, four autism centers served 2981 ASD children.

“Asyl Miras” autism centers use M-Chat and ADOS-2 for screening and diagnosis and ABLLS to conduct functional analysis. There are seven intervention programs provided for ASD children:

1. Early Intervention Program for children aged 0–3 years old
2. Language Program
3. Learning Program
4. JASPER Program
5. Social Skills Development Program
6. Leaving Skills Development Program
7. Intense course for parents

The public foundation “Ashyk Alem” promotes inclusive education in Almaty and Astana cities. “Ashyk Alem” uses ABLLS for making functional analysis. It trained limited number of tutors. Other foundations providing some supports/services include the Corporate Foundation and Orda (for sports activities) and DOM (information supports for parents).

Overview of Research Directions

Research at present is extremely limited and mostly is conducted by faculty members of Nazarbayev University (<https://nu.edu.kz>). Ongoing projects include development of a national registry, projects on providing information to parents, and some aspects of genetics.

Overview of Training

Training opportunities are limited and most training is provided by external trainers. These provide some training for clinical staff. For example, Bulat Utemuratov Foundation provided more than

30 trainings for its 120 clinical therapists during 2016–2017, inviting trainers from the USA and Russia. Trained therapists of Asyl Miras autism centers provided more than ten trainings in 2016–2017 for specialists of regional departments of the State Republican Psychological-Medical-Pedagogical Committee on the basics of ASD, using M-Chat and ADOS-2. There are two private commercial training companies in Almaty, which provide fee-based basic ABA trainings for therapist. These companies invite Russian-speaking trainers from Russia for basic ABA trainings. No one in Kazakhstan currently has BCBA certification.

No trainings are available for teachers and healthcare professionals.

Social Policy and Current Controversies

There is limited public awareness of autism. Some of the activities of NGOs and foundations are attempting to address this. Social infrastructure is not adapted for ASD children needs and expectations. As noted about inclusive education opportunities are limited.

Kinesthetic Sense

Winifred Schultz-Krohn

Department of Occupational Therapy, San José State University, San José, CA, USA

Definition

This is the sensory experience of movement of a body segment in relation to other body segments and is differentiated from proprioception which refers to the position of a body segment in relation to other body segments. The dynamic sensory experience of reaching away from the body toward a cup or reaching toward the body to button a shirt provides examples of kinesthesia. Although frequently linked with proprioception, kinesthesia is the considered mediated by the dynamic receptors within the muscle spindle, and the proprioception or position sense is mediated through receptors in the ligament and joints. Functionally, when an individual has difficulties with processing kinesthetic sensory information, the position sense is often disrupted. Many functional daily living tasks are dependent upon the accuracy in the speed, force, and direction of movement. Handwriting is one functional task that is particularly mediated by the sense of moving the hand to form letters.

Klinefelter Syndrome

Hanna Swaab
Social and Behavioural Sciences, Leiden
University, Leiden, The Netherlands

Synonyms

KS

Short Description

Klinefelter syndrome (KS) was first described by Dr. Harry Klinefelter, an endocrinologist, in 1942. He identified a group of adults with infertility, hypogonadism, gynecomastia, and increased gonadotrophin levels (Klinefelter et al. 1942). In 1959, these symptoms were linked to the extra X chromosome in these men (Jacobs and Strong 1959). The majority, about 80% of the KS population, carry an additional X chromosome (47, XXY), while the other cases have higher grade aneuploidies (e.g., 48, XXXY, 48, XXYY), mosaic forms (a combination of normal and abnormal cell lines 46, XY/47, XXY), or structurally abnormal X chromosomes (Lanfranco et al. 2004). KS has a highly variable phenotype. Besides physical features, such as described by Klinefelter, KS can manifest itself with a variety of behavioral characteristics, including developmental language problems and language-based learning disabilities, executive and attentional dysfunction, and motor developmental delays (Geschwind et al. 2000). Social function is known to be a vulnerable area of development in

KS (e.g., Mandoki and Hoffman 1991), while intellectual abilities are generally within the average range (Boada et al. 2009).

Categorization

Klinefelter syndrome is a de novo occurring genetic disorder.

Epidemiology

Klinefelter syndrome is the most frequent sex chromosomal disorder in the male, with a prevalence of 1: 600–700 in newborn boys (Bojesen et al. 2003). The extra X chromosome(s) in Klinefelter syndrome result(s) predominantly from a nondisjunction during meiosis; about halve of the cases are paternally derived, hence the other halve maternally. Very seldom Klinefelter (mosaic type) results from an error at an early mitotic division in the very early developmental stage of the embryo. Many boys and men with KS remain undiagnosed. Abramsky and Chapple (1997) calculated that about 10% of expected cases were identified prenatally (during prenatal screening) and 26% were diagnosed in childhood or adult life because of hypogonadism, gynecomastia, or infertility, leaving 64% undiagnosed. A large Danish national registry study confirms that KS is widely underdiagnosed, with less than 10% of the expected diagnoses made before puberty (Bojesen et al. 2003) and only about 24% identified in adulthood.

Natural History, Prognostic Factors, Outcomes

The impact of sex chromosome trisomies on brain function is typically mild compared to the impact of duplication of an autosome, which is typically lethal or associated to major cognitive impairments. When additional X chromosomes are present, one is predominantly inactivated. As the number of X chromosomes increases, the phenotypic severity increases as well.

A large part of the Klinefelter population goes undetected, probably because of relatively mild problems or because clinicians do not associate physical, behavioral, or emotional problems during development or in adulthood to this specific condition. The presence of an extra X chromosome often goes undetected in childhood, unless chromosome studies are undertaken to establish the etiology of educational or behavioral difficulties. Especially the mosaic type, with a milder phenotype, can go undetected.

The diagnosis is commonly made in adolescence or adulthood; gynecomastia, hypogonadism, or infertility may lead to the detection of the extra X chromosome. Klinefelter syndrome accounts for 3% of male infertility (Abramsky and Chapple 1997). Behavioral and emotional problems that can be associated with Klinefelter are not very specific.

Based on birth cohort studies with prospective design and long-term follow-up, it is concluded that there is an increased risk for medical, psychological, social, and educational difficulties in KS. Cognitive deficits are generally mild, and mixed results are reported with respect to the risk for psychopathology. Moderate to severe problems can be found in reading, spelling, and writing. Males with KS tend to leave school earlier and achieve a lower educational level than unaffected males.

Clinical Expression and Pathophysiology

Physical Features and Medical Risk

The phenotype of Klinefelter syndrome is highly variable. In KS, there are no facial characteristics. Because most boys with KS appear similar to boys with normal karyotypes, the disorder typically is identified in adolescence or adulthood. The most overt phenotypic features of Klinefelter are caused by testosterone deficiency and directly or indirectly by unsuppressed follicle-stimulating and luteinizing hormones. Affected men typically present with a tall stature, infertility, small testes, decreased facial hair, gynecomastia (in about 50%), decreased pubic hair, and a small penis. Because of their long legs, men with Klinefelter

syndrome are often taller than predicted based on parental height. Persistent androgen deficiency in adulthood may result in loss of libido, decreased muscle bulk and tone, decreased bone mineral density, a propensity for thromboembolism, and an increased risk for diabetic and cardiovascular complications (Wattendorf and Muenke 2005). However, the clinical picture of XXY males may range from severe signs of androgen deficiency, or even a lack of spontaneous puberty, to normally virilized males who only consult a doctor because of their infertility. In childhood, ascertainment is difficult, because the effects of hypogonadism (small external genitalia and firm testes) may be subtle or not present at all.

Psychopathology

In addition to the physical findings, children, adolescents, and adults with KS may present with a variety of developmental and behavioral features that make up the behavioral phenotype of KS. Based on birth cohort studies it is concluded that KS is associated with an increased risk for verbal cognition and language impairments, reading disabilities as well as behavioral and cognitive difficulties such as attention problems, executive function problems, shyness, social withdrawal, and social difficulties. The cognitive phenotype of KS does not reflect a general decline in intellectual abilities, but, rather, deficits in specific domains of cognition, namely, language and frontal-executive functions.

Systematic review of neurocognitive outcome in patients ascertained at birth by newborn screening showed overall mean cognitive abilities on standardized tests of intelligence to be in the average range; however, mean verbal cognitive scores were approximately 10 points lower than performance scores and significantly decreased in relation to typical developing children. Within the Klinefelter population, intelligence scores have a normal distribution, but the mean score is shifted slightly to the left of the population mean, at low average and borderline range (e.g., Tartaglia et al. 2010).

Specific aspects of cognitive and behavioral outcome are studied in samples of KS that were recruited in clinics or support groups,

ascertainment bias is a weakness of those studies and the results do not necessarily represent the entire spectrum of outcomes seen in KS. However, these studies draw attention to the developmental risk of boys and men with KS.

Language developmental problems are typically first observed as delay in early expressive language and speech milestones. Difficulty in articulation is found, as well as problems in word-finding and phonemic processing. Academic difficulties, related to language abilities, are found in 70–80% of KS boys. Moderate to severe problems can be found in reading, spelling, and writing. Fifty to seventy-five percent of the children meet the criteria of dyslexia (e.g., Bender et al. 1993); 92% have difficulty in learning to read (Geschwind et al. 1998). Language-related academic problems may result in problems in arithmetic and other areas of academic function, probably due to difficulty in problem-solving skills and integration of knowledge.

Especially difficulty with auditory processing and verbal memory problems are supposed to underlie the academic problems (Graham et al. 1988). Difficulty with decoding of words and sentences seem to be the problem in understanding written or spoken language. Studies report a large part of the KS population to have difficulty in verbal learning, word-finding, and verbal fluency. They also show average or above-average scores on tasks for visual-spatial information processing and visual memory. Most boys with Klinefelter syndrome show slow information processing, like most children with dyslexia, in both visual and verbal modalities.

Not much systematic research is done in the area of frontal executive functioning in longitudinal studies of KS. In addition to anecdotal evidence of hyperactivity and distractibility, several studies suggest impairments in concentration, short-term memory, and problem-solving abilities (e.g., Geschwind et al. 2000). Difficulties in attention regulation in boys with KS are reported, as well as difficulties in inhibition, although not always replicated. Inhibition problems and problems in mental flexibility appeared to be related to schizotypal traits in XXY in a study by Van Rijn et al. (2009).

Developmental motor delay is often anecdotally reported. Sports do not seem to be very popular in boys and men with KS. In the Denver birth cohort study, 8 of the 14 boys with KS had delayed independent walking. In a group of more than 30 adolescents with XXY, neurological evaluation showed mirror movements in 40% of the population and a high incidence of positional tremor. Mirror movements suggest a disruption in interhemispheric sensory-motor integration at the level of the supplementary motor area of the anterior corpus collosum, through which right and left motor regions communicate. Fine motor integration, bilateral coordination, visual motor control, and response speed were decreased in 93 predominantly prenatally diagnosed boys with KS (Ross et al. 2009).

Generally, boys and men with KS are described as introverted, shy, with high levels of anxiety and social withdrawal (e.g., Mandoki and Hoffman 1991). This may affect self-esteem and daily functioning. Several studies indicate a high risk for psychosocial problems, psychosis, and bipolar disorder in KS (e.g., Bender et al. 1999). KS is associated with the risk for autistic features and with high levels of schizotypal traits and schizophrenia symptoms (Bruining et al. 2009; van Rijn et al. 2008). Social difficulties and vulnerability for autistic traits are found in adults with KS. Men with KS show increased levels of distress during social interactions and difficulty in expressing emotions to others and in initiating contact with others. The level of autistic traits on the Autism Spectrum Quotient is higher in this group compared to the general population. Social cognition appears to be at risk in KS. Men with KS show difficulty in perception of facial emotions. They experience increased levels of emotional arousal, yet they are less able to identify and verbalize their own emotions. In addition, KS men show difficulty in discriminating emotions in verbal content of speech and in tone of voice. In a cohort of 51 boys with KS of which 50% were identified by prenatal screening, language disorder was found to be most prevalent (65%), followed by attention-deficit disorders (ADHD) and autism spectrum disorders (27%). Behavioral

impairment was most evident in cases classified with psychotic disorder (12%) (Bruining et al. 2009).

Pathophysiology

Language is distributed in and around the perisylvian cortex of the left hemisphere in most people. Developmental language disorders, such as dyslexia, have been associated with functional and anatomical patterns of anomalous dominance. Several findings suggest left hemisphere dysfunction in KS. The high incidence of fine motor mirroring in KS supports the notion that interhemispheric sensory-motor integration is anomalous. The problems in rapid auditory processing in KS are supposed to reflect suboptimal left-hemisphere function. Right ear dominance was less present in KS in dichotic listening to verbal material (Netley and Rovet 1984). These findings suggest left hemisphere dysfunction in KS.

Sex steroids have organizational effects on the central nervous system during development. Especially during fetal development, the influence of sex steroids on cognition is large. One therefore may hypothesize that differences in cognitive abilities in KS may result, in part, from differences in gonadal steroid levels during critical periods in fetal development. In KS, however, androgen deficiency is usually not present until late in adolescence when incomplete secondary sexual development may be seen in half of the KS men (Mandoki and Hoffman 1991). Serum testosterone levels at age 16–18 are within the normal range for 50% of the KS boys. There is no evidence so far for low or high intrauterine testosterone in cord blood, nor is there any attenuation of the normal postnatal rise in serum testosterone in KS infants (Ratcliffe et al. 1994). So far, no systematic research has been done to assess the influence of testosterone on cognitive development in KS and it is not likely that testosterone level can explain the total range of cognitive and behavioral differences in KS (Geschwind et al. 2000).

Cognitive and behavioral difficulties in KS might be related to a gene dosage effect based on the presence of an extra X chromosome. Expression of extra copies of genes residing on the

X chromosome leads to so-called gene dosage effects. There is evidence that a gene on the X chromosome contributes to cerebral laterality and language laterality in the normal population. Imprinting effects have been suggested to be important in social cognition. Parent-of-origin effects on social behavior seem to be associated to specific effects on autistic and schizotypal traits in one study so far (Bruining et al. 2010). Further research is necessary.

Structural and Functional Imaging Findings

Studies so far report discrepant findings from structural and functional MRI studies in KS, due to differences in study design, cohort characteristics, and neuroimaging analyses methods.

MRI results of a prospective follow-up study in a small group of KS men showed significantly smaller whole brain volume and increased volume of the ventricles (Warwick et al. 1999). Reduced total brain volume has been replicated in several studies, though other investigators have found no differences. In the Denver cohort study, the overall brain volumes of 10 KS men did not differ from controls; however, amygdala volume appeared to be smaller. Other studies also reported evidence for specific regional changes, finding small amygdala, hippocampi, STG (superior temporal gyrus), and caudate nuclei. Several studies suggest that frontal and temporal lobe volumes may be smaller in KS than in typical males. Some studies suggest that the lobar differences might be more specific to the left side, specifically in the temporal lobe, which would correspond with the specific phenotype that includes language and executive dysfunction. Functional imaging studies so far are very scarce and show a relative increase in right-sided cerebral activity with a resulting leftward asymmetry, particularly in temporo-parietal regions. KS men appear to display decreased activation in the amygdala and fusiform gyrus when judging faces (van Rijn et al. 2008, 2011).

In summary, the presence of an additional X chromosome in males does appear to have effects on both brain structure and function, in at least a subset of individuals. Decreased lateralization is found compared with controls.

Evaluation and Differential Diagnosis

Klinefelter syndrome has a highly variable phenotype and presents with mostly nonspecific behavioral problems in childhood. Developmental language problems and language-based learning disabilities (especially dyslexia) may be present as well as attention problems, executive function problems and motor developmental delays. Developmental problems, including social problems in KS, may meet the diagnostic criteria for language disorder, attention deficit disorder, autistic spectrum disorders, or other disorders like psychotic disorders. In adolescence and adulthood, physical features like hypogonadism and infertility may lead to the diagnosis of KS. KS should be specifically differentiated from dyslexia, developmental language disorders, autism spectrum disorders, and psychotic disorders.

Treatment

A suspected diagnosis can be based on the combination of typical clinical findings. The most important physical features are very low testicular volume and firm consistency of the testes, although these may not be present in all cases. Testicular volume seems to be the most sensitive indicator. In a cohort of 309 suspected cases based on the above characteristics, diagnosis could be confirmed in 28% by chromosome analysis (Lanfranco et al. 2004). In childhood, physical features hardly ever lead to the diagnosis. Physical differences in males with Klinefelter often are evident after the onset of puberty. Late or incomplete puberty should prompt further examination. The most important behavioral features appear to be in the domain of language developmental delay, specific language-based learning disabilities, attention and executive function deficits, and social adaptation problems. Clinical suspicion warrants diagnostic investigation to ensure appropriate surveillance for testosterone deficit. Chromosome analysis is necessary for the diagnosis of Klinefelter.

As soon as Klinefelter is detected, a comprehensive neurodevelopmental evaluation is recommended. Children with KS should have a

neuropsychological evaluation in early grade school to identify any symptoms of language problems, learning disabilities, attention deficits, or executive function problems. Concerns about social skills should lead to evaluation by a psychologist with sufficient experience to consider the influences of language deficits and neurocognitive problems on social development and who can perform a diagnostic assessment for autism spectrum disorders, if needed. In childhood and adolescence, a multidisciplinary developmental examination may help determine appropriate treatments such as physical therapy, speech therapy, and stimulation programs.

The prepubertal testosterone deficits results in impaired bone mineral density and skeletal muscle development. Androgen therapy should be started when there is laboratory evidence of a testosterone deficit, at about the age of 12–14. When testosterone serum concentrations in individuals with KS are low, lifelong substitution therapy is indicated and should be started in puberty to avoid symptoms and sequelae of androgen deficiency. Testosterone replacement results in increased masculinity, strength, libido, bone mineral density, and body hair. It has a positive effect on mood and behavior, improves self-esteem and reduces fatigue and irritability.

It is critical that boys with KS are provided with appropriate educational interventions that target their learning challenges in school. Psychoeducation can improve understanding of developmental and behavioral vulnerabilities. In individual cases, psychotherapy or social training can be indicated.

Kolvin, Israel (Issy)

Adam Feinstein

Autism Cymru and Looking Up, London, UK

Major Appointments (Institution, Location, Dates)

Professor of child psychiatry, Newcastle University 1977–1990; John Bowlby Foundation professor of child and adolescent mental health, Royal Free Hospital Medical School, London, 1990–1994; and emeritus professor of child psychiatry, 1994–2002.

Major Honors and Awards

Chair of the Association for Child Psychology and Psychiatry, 1994–1996.

Landmark Clinical, Scientific, and Professional Contributions

While in Oxford, working with Kit Ounsted, Kolvin carried out a particularly important study comparing children with autism and those with psychotic disorders such as schizophrenia. Prior to this work, there had been considerable confusion about the status of autism as a psychotic or a developmental disorder, and Kolvin's (1971) paper – still quoted today – clarified the issue considerably and, with other studies, firmly established autism as a developmental condition.

After his appointment as consultant in charge of the Nuffield Psychology and Psychiatry Unit in Newcastle upon Tyne in the mid-1960s, he carried out the so-called Thousand Family Study to study the effects of social deprivation and disadvantage from one generation to the next. He was able to show significant movement over time toward improved social conditions in a number of individuals. Another of his achievements in Newcastle

was an evaluation of the effectiveness of different forms of psychotherapy delivered in schools. This was groundbreaking work published in an influential book, *Help Starts Here* (1981). Many believed psychotherapy was not capable of evaluation, but this study demonstrated not only that it was possible but that meaningful results with significant implications for practice could be obtained.

Kolvin had been appointed to a personal chair in Newcastle in 1977 to become one of the first chair holders in child psychiatry. In 1990, he made a bold late career move when he was appointed to the John Bowlby chair of child and family mental health jointly held at the Royal Free Hospital and the Tavistock Clinic in London. A multicenter (London, Athens, and Helsinki) study of the effectiveness of psychotherapy in depressed children and a comparative study – published only a fortnight before Kolvin's death in 2002 – of two types of psychotherapy applied to sexually abused girls are particularly notable.

Short Biography

Born in Johannesburg, South Africa, in 1929, Israel (Issy) Kolvin worked on the wards and in the admitting room of Baragwanath Hospital in Soweto as a young doctor. The malnutrition on the children's wards and the severe psychiatric conditions presenting in the emergency room both made a profound impression on him. With few training opportunities open to him in South Africa, Kolvin obtained a place on a psychiatric training scheme in Edinburgh, Scotland.

He died in London on March 12, 2002, at the age of 72.

IEP	Individualized educational plan
MENA	Middle East and North Africa
PDD	Pervasive developmental disorder
PEP-3	Psychoeducational profile – 3rd edition
TTAP	TEACCH transition assessment profile

Historical Background

As a mother of a child with autism, Dr. Samira Al-Saad was unable to enroll her child in the education system of Kuwait when she was diagnosed with autism in 1985. With lack of awareness and knowledge about autism in her country at that time, she decided to pursue her studies in autism in the USA and shift from her specialty in geology which cares for rocks and oil to autism. She was able to earn a master’s degree and PhD degree in the field of autism. The first class started at her home in 1988 and tried unsuccessfully to convince the educational authority to start a school for such handicapped. She moved to Saudi Arabia during the invasion of Kuwait where she started (1992) her second classes as an experimental model. After 2 years, she moved back to Kuwait, and, with the cooperation of the Public Endowment Foundation, she was able to establish the first integrated center for educating children with autism in the MENA region.

The program started with basic educational facilities and focused on extensive training done by professionals from all around the world. The program extended its services throughout the year to include other basic areas such as teacher and parent training and vocational training and diploma in cooperation with well-known universities. As a result, the number of children increased from 6 in 1994 to more than 140 in 2013 and more numbers in other services. The diagnostics unit started at 1997 with well-known international professionals who helped to cover the area of diagnosis which cooperates later with developmental units in the government hospitals.

Legal Issues and Mandates for Services

Services in Kuwait for special needs started long ago since 1955 for blindness, hearing impairment, mental retardation, paralysis, and Down syndrome, but not for autism. When Law No. 13/96 was issued and the Higher Council of Handicapped was established in Kuwait by

which each child has the right to be educated and trained in government schools, and if the program is not available, then all their educational fees will be covered by the council. This encouraged private schools to open few classrooms within their schools for special needs including autism. Nevertheless, some private schools provide day care services rather than educational services and training for children with autism. But by time and more support for the budget of these schools from the council, their programs are getting better, especially when Law No. 8/2010 for the rights of people with disabilities was unanimously accepted by the Kuwaiti parliament.

In addition to educational fees of students, the council covers social help for the families who have a child with autism, if needed.

Overview of Current Treatment Options and Centers

Training using structured teaching, ABA, and sensory integration theories varies from school to school. In the Kuwait Center for Autism, the REACH philosophy was created where we use our experience and the international theories or part of them that work with our children and culture:

- R:** Relationship-focused and its enhancement.
- E:** Environment of the child and its structure are conducive for their development.
- A:** Activities designed to each child level and age through curriculum and continuous assessment.
- C:** Communication focus on the individual level.
- H:** Health enhancement of the child through a special program that is focused on integrated health.

As for awareness which started from 1995 until now with new ideas every year, as creating the Gulf Autism Union in 2002 which includes Qatar, Bahrain, the United Arab Emirates, and Oman and Kuwait as leading this union. The well-known outcome of this union came with success in 2008 when they raised the request to the United

Nations to celebrate World Autism Awareness Day internationally on the 2nd of April to which the United Nations agreed. From then on the whole world started celebrating and presenting autism campaigns. In Kuwait a lot of newspaper advertisements, meetings, and reports were done, and messages on buses which roamed around Kuwait roads carried autism information. A lot of lectures and parties were done yearly in cooperation with the Ministry of Education and Ministry of Health in April.

Research Activities

Research was one of the main goals since the Kuwait Center for Autism was founded. The research is carried in close collaboration with other parties to cover any shortage in medical or scientific professionals whether in or outside Kuwait. Some of the researches published in well-known scientific periodicals or journals in the world:

The Identification of Training and Educational Needs for Autistic Children from Parents' Perspective in Kuwait and Saudi Arabia (Samira Al-Saad, Ph.D., *Educational Journal of Academic Publication Council of Kuwait University, Vol. 12, No. 45, Autumn 1997 (Arabic)*), **Implementation of an Educational Program for Children with Autism: The Case of Kuwait** (Samira Al-Saad, Ph.D., *International Journal of Mental Health, Vol. 29, No. 2, Summer 2000*), **Biological Correlates of Childhood Autism: "Trace Elements"** (Abdullahi Fido, MD, MRCPsych, DPM & Hussein Dashti, MD & Samira Al-Saad, Ph.D., *Trace Elements and Electrolytes, Vol. 19, No. 4, Page 205–8, 2002*), **Toxic Trace Elements in the Hair of Children with Autism** (Abdullahi Fido, MD, MRCPsych, DPM & Samira Al-Saad, Ph.D., *Autism (Journal of Sage Publications & NAS), Vol. 9(3), Page 287–296, July 2005*), **Dental Care of Children in Kuwait Center for Autism: A Preliminary Study** (Samira Al-Saad, Ph.D., & H. Al-Omar, F. Ebrahim, B. Joseph, Faculties of Dentistry, Kuwait University, 2005), **Body Mass Index of Children with Autism in Kuwait** (poster)

(Abdullahi Fido, MD, MRCPsych, DPM & R. Varghese, MD & Samira Al-Saad, Ph.D., 2006), **Establishing Programs for People with Autism in Kuwait and the Gulf Region (poster)** (Samira Al-Saad, Ph.D., *Autism Safari – Cape Town Conference – 2006*), **Olanzapine in the Treatment of Behavioral Problems Associated with Autism. An Open-Label Trial in Kuwait** (Abdullahi Fido, MD, MRCPsych, DPM & Samira Al-Saad, Ph.D., (*Med. Principles Practice*.)17:415–418, 2008), and **Psychological Effects of Parenting Children with Autism** (Abdullahi Fido, MD, MRCPsych, DPM & Samira Al-Saad, Ph.D., (*International Open Journal of Psychiatry*), 2013)

Training

Major training programs are conducted by the Kuwait Center for Autism (more than 190 in 18 years). Different subjects were presented as:

- Understanding autism; play therapy; ABA; structured teaching; diagnostic tests: PEP-3, TTAP, DISCO, ADOS, and GARS; behavior aspects and its effects; art therapy; music therapy; Makaton (alternative communication system); portage; how to design IEP to the parents' expectation; AIT; sound beam and how it works with autism; International Conference 1 (Feb. 14–16, 2000); International Conference 2 (Dec. 9–11, 2003); helping parents cope the stress of having a child with autism; first aid workshops; developing social communication skills; Asperger; environmental aspects and autism; adulthood and autism; REACH philosophy; seizures and autism; how to communicate with your child; vocational trainings; creativity in educational activities; and ASDAN diploma for students.

More than 75 books were published in Arabic language for specialists, parents, siblings, etc.:

- Teaching Children with Autism to Mind-Read
- Supporting the Families of Children with Autism

- Autism: Medical and Educational Aspects
- A Comprehensive and Easy-to-Read Guide to the Most Current Research and Medical Therapies for Autism and PDD
- Understanding and Teaching Children with Autism
- Children's stories such as Captain Tommy, My Brother is Different, Autistic Planet, etc.
- Assessments such as GARS, PEP-R, AAPEP, and ABLLS-R

All of the above to maintain *our vision*:

- Leaders and pioneers in improving the future for autism in the Middle East

and *our mission* is to:

- Care and love
- Teach and train
- Development and research
- Family and community

L

Label

Moirá Lewis
Speech-Language Pathologist, Marcus Autism
Center Children's Healthcare of Atlanta, Atlanta,
GA, USA

Synonyms

Naming; Tact

Definition

A label is a *name or vocabulary item* used to refer to a particular object, person, or concept. Approximately 70% of children's first words are labels. Typical toddlers tend to transition from sounds and babbles to labels at approximately 12 months of age. Through the second year of life, they acquire a range of labels, as well as words with other functions, such as action words (verbs), descriptors (adjectives), and greetings.

For young children with autism whose language is delayed or is developing atypically, labeling may be a relatively strength. Children may say the names of objects without directing their labels to others in or to communicate, or moving towards more meaningful connected speech. A child with ASD may have a large vocabulary of labels but

may not use them for social purposes (e.g., requesting or conversing).

Lag Schedules

Christina Fragale

University of Texas at Austin, Austin, TX, USA

Definition

Lag schedule is a type of differential reinforcement schedule used to promote the variability of behavioral responses or sequence of responses. On a lag schedule, reinforcement is delivered for a response that is different from a specified number of preceding responses. The schedule is denoted as Lag x in which the x refers to the number of previous responses the current response needs to differ from in order to be reinforced. For example, on a Lag 3 schedule, reinforcement will be provided on the fourth response, only if it is different from the three preceding responses. If the current response is not different, it is then included as one of the preceding responses, for the next response. Therefore, the lag “window” is constantly changing. For example, on a Lag 3 schedule, if a person is asked, “Name an animal that has a tail,” and answers “cat,” “dog,” “tiger,” “horse,” the last answer “horse” would result in reinforcement because it is different from the previous three responses. However, if the person says, “cat,” “dog,” “tiger,” “dog,” the last term would not result in any reinforcement because it is the same as one of the three preceding responses. The person could then say “cat” or “horse” because the lag window is now “dog,” “tiger,” “dog,” and either answer (“cat” or “horse”) would be different from these responses.

Historical Background

Lag schedules have been used as one of the ways to study and improve response variability of behavior. Response variability (or behavioral variability) refers to responses or sequences of responses that are different from each other. High variability of behavior may appear to be unpredictable or even random. Low variability

of behavior may be repetitive or look very similar. Although researchers began to explore in the 1960s whether response variability could be influenced through environmental changes (Pryor et al. 1969; Goetz and Baer 1973), lag schedules were not proposed in the literature until over a decade later, by Page and Neuringer (1985). At the time, variability of responding was recognized as a “side effect,” produced as a secondary characteristic of reinforcement schedules (e.g., intermittent schedules of reinforcement in which extinction produced increased response variability), but there was not a consensus as to whether behavioral variability could be *reinforced* as an operant behavior. Page and Neuringer set out to study exactly this by conducting a series of experiments to establish whether lag schedules could be used to increase response variability in pigeons. They demonstrated that pigeons could not only meet requirements for a Lag 1 and Lag 5 schedule but were also successful on a more sophisticated Lag 50 schedule. Their results supported the idea that variability could be directly reinforced. Page and Neuringer also reported that variability could be brought under stimulus control. They showed that the pigeons emitted higher variable responding when a blue light was on and a repeated sequence of pecking when a red light was on (and then successfully switched light assignments where variable responding was cued by the red light and repeated responding by the blue light). This demonstration of stimulus control of variable responding provided additional support that response variability could be an operant behavior. This seminal article was a catalyst for research aimed at increasing response variability using lag schedules of reinforcement.

Applied researchers of behavior analysis began to investigate the use of lag schedules with human populations, namely, those with autism spectrum disorders (ASD), in the 2000s. For example, Lee et al. (2002) demonstrated that a Lag 1 schedule paired with differential reinforcement of alternative behaviors (DRA) increased appropriate varied verbal responding to the social question “What do you like to do?” when compared to DRA alone. This was effective with two of the three male

participants and was one of the earliest demonstrations of lag schedules utilized with people.

Current Knowledge

Inflexible adherence to routines and engaging in repetitive patterns of behaviors, interests, or activities are some of the hallmark characteristics of ASD. Research indicates that children with ASD respond in ways that do not maximize reinforcement when compared to similarly aged children who are not on the autism spectrum. Instead, children with ASD tended to repeat or stay within a subset of choices rather than sample all of the offered choices leading to reinforcement. With the increase in developing interventions and strategies for individuals with ASD and fundamental need to increase response variability for this population, the application of lag schedules has led to an explosion of research in more applied contexts and settings within recent years.

Behavioral therapists should focus on improving response variability because response variability can be functional and adaptive. For example, response variability can aid in problem-solving. When the typical response is not sufficient to solve a problem, the person may be required to try other potential solutions rather than engaging in the same behavior repeatedly. Creativity is another example of when variability might be beneficial. Creativity may be conceptualized as novel responses that deviate from the status quo. Finally, a fundamental component in behavior-shaping procedures (i.e., new behaviors or skills are taught by reinforcing approximations of behaviors until the final target behavior is reached) requires a person to provide variations of the target response. If the person does not offer different approximations, reinforcement criterion will not be met, and shaping will not be successful. Behavior that is seemingly unpredictable or variable has traditionally been thought to be an uncontrollable or an internal characteristic to human nature. However, recent behavioral research indicates that behavioral variability could be an operant characteristic of behavior. In other words, variability of behavior can be

increased, maintained, or decreased through the environmental contingencies of reinforcement and extinction (Page and Neuringer 1985). This could be significant in developing effective interventions for individuals on the autism spectrum.

Lag schedules are one way to improve behavioral variability and only recently begun to be studied in applied contexts. Most of the studies focused on individuals with ASD and lag schedules are centered around testing the feasibility of lag schedules with various skills. Researchers have explored increasing response variability with people in toy play (Baruni et al. 2014; Lang et al. 2014), verbal responding to social questions such as “What do you like to do?” or “How are you?” (Lee et al. 2002; Lee and Sturmey 2006; Susa and Schlinger Jr 2012), building verbal tacting or intraverbal repertoires (Contreras and Betz 2016; Heldt and Schlinger 2012), increasing vocalizations for children with little echoic responding (Esch et al. 2009; Koehler-Platten et al. 2013), using sign language to mand (Silbaugh and Falcomata 2019), functional communication training (FCT; Adami et al. 2017; Falcomata et al. 2018; Muething et al. 2018), and improving feeding for children with limited food repertoires (Silbaugh et al. 2017).

Many of the current studies to date have demonstrated the use of fairly low lag schedules (i.e., Lag 1 to Lag 3) with people with ASD. For most of the participants, these simple lag schedules have been sufficient for increasing variability in responding. However, some participants required additional prompting in order to see increased variability. There is no consensus among researchers as to who would benefit from lag schedules and who would require the additional supports.

There may be some situations in which the general socially acceptable response would be to respond in a variety of ways but other times in which repeated behavior would be warranted. For instance, if two people meet for the first time, it would be socially acceptable to introduce themselves or ask the other person's name the first or even second time upon meeting. However, after multiple meetings, it might be frowned upon to continue to ask the other person what their name

is. Another context in which varied behavior is more accepted is joke telling. A person generally finds a joke funny the first time the joke teller says the punchline, but may not find it funny if the joke teller repeats the joke a second or third time. It could even be that the social acceptance for the joke teller tends to wane. In contrast, there are situations in which repeated behavior might be more beneficial than varied behavior. There is no shortage of successful people who value their morning rituals or routines to set the day, for example. Habits are behaviors that are so repeated or perfected they are nearly automatic, such that a person does not need to dedicate the mental capacity to engage in the behavior and can instead focus on other important decisions. A professional athlete's success may hinge on their ability to repeatedly perform at a high level, under considerable pressure. Therefore, the advantages of variability and repeated behaviors may be contextually dependent. Scientists in the basic behavioral sciences have demonstrated that variability may be brought under stimulus control in which a stimulus is paired with the lag schedule to increase variability. When the stimulus (colored cue card) is present and the lag schedule in play, the subject offers varied responding, whereas when a different stimulus is presented and a non-lag schedule used, the subject returns to less varied responding. While this type of responding has been shown to occur also with individuals with ASD, the cues have been obvious and contrived. A more naturally occurring clinical application for stimulus control with lag schedules has not been reported.

Future Directions

Since the majority of applied research on lag schedules have been conducted in the last decade, current results are promising but continue to be limited in our understanding to the clinical use of lag schedules with individuals with ASD. Much of the current research with human populations have been translational in nature, as researchers try to use what is currently known from basic behavioral research and understand how lag schedules might be applied to people. Therefore,

researchers may continue to focus on how to develop lag schedules specifically to improve people's lives.

Parameters of Lag Schedules in Applied Settings

Although there seems to be some indication of potential clinical utility to using lag schedules with individuals on the autism spectrum, questions about the parameters of this schedule of reinforcement remain. For instance, in some studies with human participants, the lag contingency was removed and variability of behaviors continued. In other cases, lack of variability returned when lag schedules were removed. Future research might explore the durability of varied behavior when lag schedules are used. While we hope that a person could learn to vary their behaviors in contexts in which varied behavior benefits him or her, does a lag schedule of reinforcement need to always be in effect to do so? At what point could a more natural, less stringent intermittent schedule be utilized and still maintain variability?

Research in applied settings have mainly utilized smaller lag schedules (e.g., Lag 5 or less). It would be beneficial to know whether there is any advantage to using higher lag schedules (e.g., Lag 10). For instance, although Lag 50 has been used with pigeons, it may not be clinically advantageous or even feasible to use such a large lag schedule with human populations. Preliminary results by Falcomata et al. (2018) indicate that there could be "ceiling effects" in which there is not a substantial variability improvement with higher lag schedules. This is an area that requires future research.

Social Validity of Lag Schedules

With applied research, procedures that are feasible or efficient also require social acceptability in their use. In the development of lag schedule applications, researchers should define guidelines for determining the level of variability that is socially desirable and appropriate when using lag schedules. Of the various methods for improving variability (e.g., extinction, percentile schedules, reinforcing novel behaviors), researchers should outline the benefits and drawbacks to

using lag schedules over other methods. In addition, most, if not all lag schedule research to date, has been conducted by researchers as implementers. A logical step for future research might be to understand how caregivers, clinicians, or teachers could effectively utilize lag schedules in various settings such as in a home or school/classroom setting.

Prerequisite Repertoires for Using Lag Schedules

When using lag schedules, responses are reinforced if they are different from a set number of preceding responses. Because this “window” is always changing as responses are offered, smaller lag schedules (e.g., Lag 1 or Lag 2) have resulted in the potential drawback of “higher-order stereotypy” in which the same few responses are given to meet the lag criterion. For example, on a lag 1 schedule, two responses could be alternated repeatedly and still result in reinforcement. While variability would be achieved, this level of variability may not be sufficient. Therefore, alternative lag schedules (e.g., lag-lag schedules, progressive vs. fixed lag schedules) that avoid higher-order stereotypy might be developed. Alternatively, larger lag schedules (e.g., Lag 5 or more) require a larger repertoire of responses to develop this window of responses. However, we do not have information on how large these repertoires need to be for lag schedules to be successful. Finally, there are questions about how lag schedules affect novel behaviors. Current research indicates that lag schedules have promoted novel responding, but these results have been inconsistent among participants. Therefore, researchers should not only explore strategies to consistently increase novel responding but also begin to understand the behavioral repertoire and participant characteristics that make novel responding more likely.

Package Interventions Using Lag Schedules

When therapists develop an intervention or clinical therapy plan for clients, they often include multiple interventions or strategies as part of a multicomponent package to affect targeted behaviors. Schedules of reinforcement might be just one

of the considerations in the intervention plan. While most of the current research has revolved around the basic feasibility of using lag schedules with human populations, as research in lag schedules continues to move forward, it will be important to understand the role lag schedules might play when combined with other intervention strategies. Are lag schedules effective when part of an intervention package? Could lag schedules enhance other interventions or vice versa? Or do they inhibit results? For example, in previous research, some participants required additional prompting to the lag schedules utilized before seeing improved variability.

Lamictal (lamotrigine)

Tanuja Gandhi
Child Study Centre, Yale School of Medicine,
New Haven, CT, USA

Synonyms

Lamotrigine

Mechanisms of Action

Lamotrigine is an anticonvulsant. It works by inhibiting voltage-activated sodium channels, antagonizes N-type calcium channels, and also has antilutamatergic action. The anti-glutamatergic effect is thought to be through inhibition of sodium, calcium, and potassium channels leading to decreased release of the excitatory amino acid glutamate. While there are studies to show potential favorable effects on cognition and mood stabilization, there is currently insufficient evidence to support the use of lamotrigine in Autism Spectrum Disorder.

Specific Compounds and Properties

Lamotrigine is an antiepileptic drug of the phenyltriazine class.

Language

Courtenay Norbury
Psychology Department, Royal Holloway,
University of London, Egham, Surrey, UK

Definition

Language may be defined as a representational rule-based system of arbitrary symbols used to convey information among members of a shared language community. Language symbols may be spoken, written, or signed and may be combined and recombined in ways that enable speakers to convey an infinite number of thoughts, feelings, and ideas. Frith and Happe (1994) distinguish language and communication; we can communicate with others without recourse to a rule-based language system through our gestures, facial expressions, eye gaze, or other actions. Similarly, an individual may possess the words and grammar of his language community but still struggle to communicate. Within ASD, communication disorders are universal, while language impairments are extremely variable (Tager-Flusberg et al. 2005).

Language is a system of five component parts. Although these may be studied separately, in reality, they are highly interactive. *Phonology* refers to the sounds of speech and more specifically to the rules that govern combining speech sounds to form meaningfully distinct words. Phonemes are the minimal units that can differentiate meaning; for example, changing the phoneme /f/ in “phone” to a /t/ creates a new word with a distinct meaning, “tone.” *Semantics* refers to word meaning and is related to vocabulary. However, semantics is more than a simple store of known words. Semantics also considers how words are connected within the lexicon; for example, understanding metaphorical

expressions such as “that lawyer is a shark” requires not only knowledge of lawyers and sharks but also an understanding of the subtle features that are shared between these two seemingly distinct entities. *Morphology* refers to the prefixes and suffixes added to words that modify meaning. For instance, adding “un” to “happy” creates a distinct word which means the exact opposite of happy. Morphemes may also signal grammatical tense; “-ed” added to the end of many verbs will indicate an activity that happened in the past. *Syntax*, or grammar, is a set of hierarchical rules that govern word combinations and sentences. For example, the sentence “the boy was kissed by the girl” cannot be understood by word order alone (i.e., “boy kissed girl”) but requires appreciation of “passive” voice so that the girl may be correctly identified as the agent of the action kiss. As noted earlier, mastery of phonology, semantics, morphology, and syntax does not guarantee communication. For instance, sentences such as “the fish is on the table” have multiple meanings, and the intended meaning may only be clear when nonlinguistic contextual factors are taken into account. *Pragmatics* refers to this use of language in context. Pragmatic abilities require interlocutors to integrate linguistic information with a variety of other factors, including general knowledge, nonverbal cues, and shared knowledge between speakers. Because pragmatics frequently relies on understanding the internal states of communication partners, this aspect of language presents particular challenges to individuals with ASD.

Language Acquisition

Rhiannon J. Luyster

Department of Communication Sciences and Disorders, Emerson College, Boston, MA, USA

Definition

Language acquisition is a process that includes the perception and understanding of language, as well as the meaningful use of it. It is generally conceptualized as referring to the initial mastery of language occurring in infancy rather than the second language learning that can occur later in childhood or adolescence.

Language acquisition progresses through a number of stages, starting very young in infancy. Particularly in the early stages of language acquisition, a distinction can be made between receptive and expressive language. Although these domains of development progress at slightly different rates early in life, the excessive divergence of these areas can be a marker of atypical development. The first task of infants is to master the sound structure used in their native language; they are born with the ability to differentiate all phonemes used in human language. Toward the first birthday, however, through “perceptual narrowing,” the infant loses the ability to perceive phonemes that are not used in their native language. During this same time period, the infant is learning to parse the sounds that they hear into predictable “chunks,” a strategy which will eventually support their learning of words.

The next phase of language acquisition is the mastery of words, both receptively and expressively. Children begin to understand the meanings of words sometime around 10–12 months, and they begin to produce them shortly thereafter. First words are similar to the world around, and they generally refer to the most important aspects of the infant’s world: caregivers, favorite foods, games, etc. The child progresses to multiple word phrases and then to complex sentences; this transition requires the mastery of syntax and grammar. Along with these vocabulary and structural

advancements comes a greater proficiency with the pragmatics – or social usage – of language.

For most individuals, language refers to verbal utterances. However, those individuals who learn a gestural language follow largely the same pattern of development. Furthermore, starting at least in early childhood, and certainly by adulthood, all language – whether first or second, verbal or gestural – is processed predominantly in the left cerebral hemisphere.

Although the timeline of language acquisition has long been known, the mechanisms by which it proceeds remain up for debate. A variety of arguments have been made to explain the rapid developments over the first few years of life. The behaviorist account was one of the earliest accounts for the emergence of language. This account was rooted in the observations made about general principles of learning and suggested that language was taught to infants much the same way that they learned any other skill: through positive and negative reinforcement. This proposal has largely fallen out of favor, although the idea that language learning is the product of general learning mechanisms is still a primary argument in these ongoing discussions. In contrast, the nativist hypothesis proposes that the capacity for language is a product of an inborn cognitive “module.” By this account, language learning is the product of a specialized cognitive structure. A hybrid account is more widely accepted today and emphasizes the importance of both inborn predisposition and environmental input in the attainment of language.

Language Acquisition Device

Lauren Schmitt
Psychiatry, UT Southwestern Medical Center,
Dallas, TX, USA

Synonyms

LAD; Language organ

Definition

The Language Acquisition Device, or LAD, was proposed by psycholinguist Noam Chomsky as the device or organ within the brain which houses human's innate ability to acquire and produce language. Stemming from the nativist theory which asserts that certain skills innately exist in humans, the LAD is thus in direct opposition with the behaviorist theory which suggests skills are attained through learning and reinforcement. According to Chomsky, the LAD is held responsible for allowing children to derive syntactic structure and rules from their native language through multiple stages of hypothesis testing. Through this process, the LAD transforms generalizations of speech and language into basic grammar. This hypothetical structure helps explain the immense surge in language ability in toddlerhood, but it is unavailable after an unspecified critical period of development.

The LAD is a theoretical construct, and therefore its relationship to language acquisition in Autism Spectrum Disorder has not been specifically tested.

Language Barriers Impact on Access to Services

Helaine St. Amant¹ and Douglas Vanderbilt²

¹UC Davis Department of Pediatrics,
Sacramento, CA, USA

²Developmental-Behavioral Pediatrics,
Children's Hospital Los Angeles/USC,
Los Angeles, CA, USA

Definition

A "language barrier" constitutes difficulty or inability for two or more people to communicate because they speak different languages. It has been shown that language barriers among parents of children diagnosed with autism spectrum disorder (ASD) have a negative impact on the child's access to and optimization of healthcare and educational services (St. Amant et al. 2017).

Data collected in a large, urban area of California suggest that children of parents whose primary language was English were significantly more likely to have both social skills and communication goals included in their individualized education plan (IEP) compared to children of parents whose primary language was not English. Additionally, children of primary English speakers received significantly more hours of direct services from their state disability program. These data were

significant despite controlling for demographic covariates such as ethnicity, race, age, and gender.

It is doubtful that these disparities in access to ASD services solely represent differences in the variable profile of ASD across primary language. Instead, they most likely reflect the heightened challenge faced by parents whose primary language is not English to advocate for specific and appropriate healthcare and educational services for their child despite this being encouraged by IDEA parts B and C.

Many studies support these and related findings, suggesting that acculturation factors such as primary language, ethnicity, and race play a significant role in access to services for children with ASD (Liptak et al. 2008). A systematic review article recently published by Singh and Bunyak (2019) identified three interdependent themes that contribute to accessing appropriate ASD diagnoses and services including familial, cultural, and structural barriers, of which language barriers were found to compound the effects of cultural beliefs on access to services by negatively impacting the process of obtaining an ASD diagnosis. Further, Zuckerman, Mattox et al. (2014) were able to identify a recurring association between racial, ethnic, and language disabilities and the ability to access ASD diagnosis and services.

It is critically important to analyze acculturation factors impacting access to services for children with ASD because it is well-documented that intensive therapeutic and behavioral services result in better outcomes for these children (Reed et al. 2007). Publicly funded, state disability programs play an integral role in improving outcomes for children with ASD, with a large majority of families confirming that the support their child received made a positive difference in their family's life according to the National Core Indicators Child Family Survey in 2013.

Furthermore, IEPs are inherently designed to be specific and appropriate for a child with special needs, and while ASD represents a continuum of social and behavioral impairments, it is reasonable to conclude that an IEP designed for the

needs of a child with ASD would include goals focused on social and communication skills, because one of the core diagnostic criteria of ASD is persistent deficits in social communication and social interaction. The conclusion that language barriers significantly impact the likelihood that these ASD-specific goals are included in IEPs therefore likely represents true inequity in access to services (St. Amant et al. 2017).

According to the National Institute of Medicine, one of the six aims for improving healthcare is equity. It is therefore a matter of public health to acknowledge and understand the origin of differences in service access in order to adequately address this fundamental problem.

LDS

Description

The *Language Development Survey* (LDS) is a widely used screening instrument, developed by

Leslie Rescorla, that obtains parent report of a child's expressive vocabulary and beginning word combinations. The LDS includes 310 words organized within 14 semantic categories (e.g., toys, body parts, food, animals, people). High-frequency words (e.g., "more") as well as less common words (e.g., "hamburger") are provided on the list. Lexical chunks (e.g., "all gone," "night night," "Sesame Street") are also listed on the LDS. When completing the LDS, parents are asked to indicate words on the list that their child spontaneously produces but also are allowed to add additional words spoken by the child. Parents may indicate words that the child produces in other languages by circling the English word on the list and writing the first letter of the language in which the child produces the word (e.g., circle "water" and write S if the child says "agua" in Spanish). Words on the list also may be circled if the child mispronounces the words or says it in "baby talk" (e.g., "baba" for bottle). In addition to identifying words that the child can produce, parents are asked if the child combines words and, if so, are asked to provide five examples of the child's best and longest sentences, from which mean length of utterance (MLU) can be calculated. Only expressive language abilities are assessed on the LDS.

The LDS is designed to be a screening instrument for language delays. It collects information regarding possible risk factors for language delays (e.g., history of ear infections, whether the parent is concerned about the child's language development, family history of delayed language development). Furthermore, norms for ages 18–35 months can be used to indicate whether a child's vocabulary and word combinations are delayed. The normative information provided for ages 18–35 also can be used for children with language delays who are older than the normative sample. The use of the LDS as a screening tool is efficient because it can typically be completed in approximately 10 min. Instructions are written on each scoring sheet and do not require additional explanation; however, it could be argued that a more detailed description of spontaneous word production could be provided. In addition, the LDS is written at a fifth-grade reading level (Achenbach 2011), making it a user-friendly tool for adults with differing abilities.

Gender-specific norms are available for ages 18–23, 24–29, and 30–35 months. Scores at or below the 15th percentile indicate delayed vocabulary development (Achenbach 2011). The commonly accepted cut point for identifying children at risk for language delay has been less than 50 words or no word combinations at 24 months of age (Rescorla 1989); thus, the survey is often administered at this age. This cut point identifies approximately 10% of toddlers in the general population.

In order to score the LDS, the total number of words circled and written in by the parents is counted. Total number of words from each semantic category can also be counted to provide more specific information about the child's lexical knowledge. In addition, if the child is combining words, clinicians can estimate MLU from the example sentences provided by the parent. Normative information for average phrase length is provided only for ages 24–29 and 30–35 months. MLU scores falling below the 20th percentile suggest delayed phrase development (Achenbach 2011).

The LDS is included in the Child Behavior Checklist for ages 1½ to 5 (CBCL/1½ to 5/LDS) in both English and a Latino Spanish language version. Translations in other languages are also available. Studies reporting findings for Latino children have been published (e.g., Patterson 1998; Seltzer 1995).

Historical Background

The LDS was created to provide a quick, reliable, and valid screening of vocabulary development in young children. The development of the LDS was based on previous studies utilizing language diaries kept by mothers and other studies assessing parent report of vocabulary (e.g., Benedict 1979). Revisions with lengths ranging from 240 to 353 words have been evaluated (Rescorla 1989) to obtain the final version with 310 words organized under 14 semantic domains. Over 1500 parents of toddlers ranging from 18 to 35 months (primarily between 24 and 30 months) varying in ethnicity and SES have completed the LDS in private pediatric clinics, inner-city hospitals,

day-care centers, family homes, and by mail (e.g., Klee et al. 1998, 2000; Rescorla 1989, 2005).

Psychometric Data

Reliability and validity data for the LDS have been reported in numerous studies. Rescorla (1989) reported 1-week test-retest reliability and Cronbach's alpha internal consistency of .99. LDS test-retest reliabilities of .97 for vocabulary score and .87 for mean length of phrases were found when mothers completed the LDS twice an average of 23 days apart (Rescorla and Alley 2001). Correlations between LDS vocabulary scores and numbers of objects and pictures named on various tests have ranged from .72 to .87 (Klee et al. 1998; Rescorla 1989; Rescorla and Alley 2001; Rescorla et al. 1993). Also, LDS vocabulary scores have been found to highly correlate with other standard measures including the Bayley Mental Development Index ($r = .79$; Bayley 1969), the Reynell Receptive Language Scale ($r = .56$) and the Reynell Expressive Language Scale ($r = .78$; Reynell and Gruber 1985), and the Vineland Adaptive Behavior Scales (composite scores $r = .71$; Sparrow et al. 1984) (Rescorla and Alley 2001).

High levels of sensitivity and specificity also have been reported in several studies (Klee et al. 1998; Rescorla 1989; Rescorla and Alley 2001; Rescorla et al. 1993), indicating validation of LDS cut points for language delay. Despite this, it has been suggested that the LDS yields a rather high false-positive rate (Klee et al. 1998). When compared to cutoff z-scores from the Reynell Expressive Language Scale, the cut point for language delay on the LDS was found to have a sensitivity score of 95% and specificity of 67% (Rescorla and Alley 2001). Therefore, a revised criterion to indicate delayed language has been suggested in an effort to reduce false positives. Klee et al. (2000) suggest using a cut point of fewer than 50 words *or* no word combinations *and* either six or more ear infections within the first 2 years of life *or* parental concerns about the child's language development for 24-month olds.

Rescorla and colleagues (2005) have compared the content validity of the LDS to the MacArthur-Bates Communicative Development Inventory: Words and Sentences Scales (MCDI-WS; Fenson et al. 1993) by having parents of over 290 typically developing toddlers complete both test protocols. At 680 words, the MCDI-WS is a longer instrument and more time consuming to complete than the LDS. However, the MCDI-WS has been widely used in studies of early language development in children with autism as well as children who are typically developing, late talkers, and those with a variety of neurodevelopmental disorders associated with language delay (e.g., Smith et al. 2007). A correlation of .95 ($p < .001$) was found between the LDS and the MCDI-WS vocabulary scores, although absolute vocabulary size was reported to be larger on the MCDI-WS. Mean phrase length as measured by the two instruments showed high agreement ($r = .90, p < .001$). Researchers wanting to make a more accurate estimate of absolute vocabulary size might choose to use the MCDI-WS, especially when assessing vocabulary skills in children within the 90th percentile. Also, researchers evaluating vocabulary size in children older than 24 months may wish to use the MCDI-WS due to frequently observed ceiling scores in children 30–32 months of age (e.g., Rescorla and Achenbach 2002). Furthermore, unlike the LDS, the MCDI-WS contains items asking about the child's vocabulary comprehension and morphological and syntactic development. Despite this, syntax scores from the MCDI-WS were shown to be highly correlated with MLU scores from both the MCDI-WS and the LDS (.81 and .78, respectively; Rescorla).

Clinical Uses

The Language Development Survey can be used as a screening tool in medical, clinical, and educational settings to provide a fast and inexpensive way to gather information about a young child's expressive language skills in order to identify children at risk for language delay.

Language Interventions

Donna S. Murray
Division of Developmental and Behavioral
Pediatrics, Cincinnati Children's Hospital
Medical Center, Cincinnati, OH, USA

Definition

Language intervention is broadly defined as "instructional interactions designed to enhance language" (Weiss 1993, p. 231). Language is described as a complex and dynamic system of conventional symbols that is used in various modes for thought and communication (American Speech-Language-Hearing Association [ASHA]

1982). Language develops through a socially and culturally accepted set of rules that govern sounds, words, sentences, meanings, and their use. There must be a common understanding of these rules in order to understand or formulate language. The effective use of language for communication requires a broad understanding of human interaction including nonverbal cues (gestures, facial expressions), motivation (a desire to communicate), and sociocultural roles (ASHA 1982). If there is a breakdown in any component of language, then effective communication is compromised.

Historical Background

Early language intervention evolved from psycholinguistic and behavioral research in the 1960s. Before that time, it was believed that intellectual ability was stable and therefore subject to little change. However, this belief was challenged by a group of researchers using principles derived from behavior analysis. These studies demonstrated good response to intervention addressing improvements in speech production in children with significant intellectual disabilities. During this time, information surfaced describing the development of language as opposed to speech production. It was in the 1970s that the first formal language programs appeared and the first conference on language intervention was held. It was also during this period that parents and caregivers were first included in language intervention programs. It was not until the 1980s that broader concepts of language and language intervention were described. These concepts included interdisciplinary models, the importance of the social aspects of language, expanding intervention to include infants and small children, the development of augmentative communication systems, and attention to the environmental context in which language is used (Bricker 1993). During the last two decades, language intervention has continued to evolve, placing increasing importance in the social and functional use of language in context. Additionally, we have observed a

greater emphasis on addressing early prelinguistic stages of language development such as the ability to attend to speech, the ability to understand and use gestures, development of joint attention, and symbolic behaviors such as play.

Rationale or Underlying Theory

Language skills are the foundation for literacy and learning skills. Communicative competence is related to the development of social behavior, reduced problem behavior, and generally more favorable outcomes. Competence in communication skills has been found to primarily determine the extent to which individuals with ASD can develop relationships and successfully participate in daily activities (Prizant and Wetherby 2005). Research has found that IQ and language competence by age of 5 are large predictors of outcomes in children with ASD (National Research Council [NRC] 2001).

Goals and Objectives

Establishing an effective communication system requires competence in language abilities. Children with autism spectrum disorders (ASD) present with deficits in broad range of language domains, including syntax (rules that govern the way words are combined to form phrases and sentences), semantics (meaning), pragmatics (social use of language), and comprehension. Additionally, individuals with ASD have specific impairments in the social aspect of language. Therefore, language intervention, in individuals with ASD, must include strategies to address the social aspects of language.

Prelinguistic Stage

Children with ASD have difficulty with the reciprocal nature of communication. At the early prelinguistic or preverbal stage of communication, language intervention in children with ASD should focus on establishing reciprocity with others. This may include activities that encourage

the back-and-forth flow of interactions (rolling a ball back and forth, peek-a-boo). These activities mirror the to-and-fro interaction of communication. Another core deficit widely described in children with ASD is a deficit in joint attention. Joint attention is broadly described as the ability to coordinate visual attention with a social partner (Munday and Burnette 2005). More recently, early language intervention for children with ASD includes addressing deficits in joint attention and recognizes this skill as a foundational skill in language development. Another core deficit in children with ASD is in the area of other symbolic behaviors. These other symbolic behaviors include difficulties in imaginative or pretend play (Rogers et al. 2005) and the impaired ability to imitate others. Language intervention programs for children with ASD should aim to improve these areas of symbolic behavior as a prerequisite to language learning.

Early Language Intervention

Early intervention in ASD focuses on attending to the speech of others and establishing a functional communication system. Individuals with autism often have core deficits in the reciprocal nature of communication. In order to establish communication, a symbolic system must be taught. This may be in the form of words, pictures, signs, as well as nonverbal communication systems such as gestures and facial expressions. Within the context of teaching a symbolic system, the reciprocal exchange, the idea that there is a giver and receiver of communication, must be taught. Additionally, children with ASD have reduced initiation of communicative acts; therefore, initiation of communication needs to be taught (NRC 2001). In addition to using language, the understanding of language including nonverbal communication should be addressed.

Expanding Language

The goal of language intervention for children with ASD, with an established verbal communication system, is to expand the means (how the child communicates) and function (why the child communicates). Children with ASD primarily use communication to request or regulate the actions

of others. Intervention at this stage focuses on expanding the variety of communicative functions while building longer, grammatically correct utterances. At this stage, intervention addresses the use and comprehension of linguistic concepts such as pronouns, adjectives, prepositions, plurals, etc. In addition to that are understanding and responding to questions, expanding vocabulary including multiple meaning words, and following single and multistep directions. Language intervention should address the use of language in social contexts such as play (Paul and Sutherland 2005).

Advanced Language

Language intervention for more advanced language learners centers on the social use of language. These skills include initiation and ending of conversations, conversational turn taking, and topic maintenance. Advanced language users with ASD have difficulties in understanding abstract language and idioms, making inferences, and recognizing conversational breakdowns and making conversational repairs. These difficulties are frequently masked by relatively intact structural language skills and vocabulary (Marans et al. 2005). Language intervention at this level frequently includes participation in social skills groups. Social skills groups create an environment that provides a more naturalistic context in which to teach the social aspect of language. These groups also allow for rehearsal of learned skills in a supportive setting with peers.

Treatment Participants

Children and adults of all ages may be candidates for language intervention. Language intervention may be initiated (a) to restore lost language abilities secondary to a traumatic head injury or stroke, (b) to maximize residual skills secondary to a degenerative disease, or (c) when a language delay or disorder is diagnosed in young children. This diagnosis may be secondary to a developmental delay or in isolation as in specific language impairment (SLI).

Treatment Procedures

There are a wide variety of language intervention approaches. These fall along a continuum in two major approaches, behavioral and developmental-pragmatic approaches.

Behavioral Approaches

There is a large body of research supporting the use of discrete trial behavioral approaches in initiating speech production and developing attention to and understanding of language. This approach is very structured and relies on adult/teacher direction. It was one of the earliest empirically based interventions for children with ASD. There have been criticisms that discrete trial approaches lead to passive response communication. More recently, behavioral approaches have evolved into what is now commonly referred to as “contemporary applied behavior analysis.” These behavioral approaches apply behavioral methods in a more naturalistic setting and address issues of initiation and generalization. There are studies that show that these more contemporary approaches are effective in improving language outcomes.

Developmentally Based

This approach assumes that children with ASD develop language in the same way and follow the same sequence as typically developing children do. In developmentally based approaches, intervention often focuses on the development of strong interpersonal relationships. The supporters of developmental approaches hypothesize that addressing key ASD-specific deficits, such as difficulty in developing interpersonal relationships, may yield broader changes in a range of behaviors. This approach often “follows the child’s lead,” allowing the child to choose the activities. The therapist creates the intervention around these naturally motivating activities, scaffolding communication and expectations as the child develops. One of the difficulties of the intervention is that it requires a great deal of creativity and decision making on the part of the interventionist. There is no prescribed protocol of intervention, so

caregivers may find the intervention difficult to carry over outside the therapeutic environment. There is some emerging research supporting developmentally based approaches primarily in the area of generalization and social aspects of language.

Efficacy Information

There is mounting evidence supporting the effectiveness of intensive early intervention with a substantial proportion of young children with ASD (NRC 2001). Intervention provided before age of 3 years has an even greater impact than intervention that is initiated after the age of 5.

The NRC (2001) indicates that the body of research supports improvements in children with ASD in response to language intervention. However, outcomes in this population are variable, with some children demonstrating substantial gains in a short period of time and others making slow gains over a long period of time.

Although there is strong support for language intervention, there is no sufficient efficacy data on specific language approaches over another. Comparative efficacy of communication approaches is often weak due to significant variability within the practice of a particular approach, and there is a lack of consideration of the overlap between different approaches, or categories of approaches (Prizant and Wetherby 2005).

Outcome Measurement

Outside of research, language intervention outcomes are frequently measured by periodic reevaluations, such as standardized tests, language or play samples, and progress against measurable objectives in the treatment plan. Additionally, caregiver and teacher reports of the functional use of language provide important information about the generalization and functional use of language across environments.

Qualifications of Treatment Providers

Speech-language pathologists are specifically trained to assess, develop intervention plans, and treat individuals with language deficits. In order to be licensed, they hold a master's degree in speech-language pathology and have successfully completed a nine-month clinical fellowship, the year following their graduation. Speech-language pathologists (SLPs) typically take the lead in the assessment, development, and implementation of language intervention programs. However, there are a variety of professionals that additionally address the language needs of children with ASD. Because intervention needs to take place across a variety of environments for learning and generalization of skills, SLPs work closely with caregivers, educators, psychologists, and other related professionals in enhancing language development across environments.

Language Tests

Geralyn Timler

Speech Pathology and Audiology, Miami University, Oxford, OH, USA

Synonyms

[Norm-referenced assessment](#); [Norm-referenced testing](#); [Standardized tests](#)

Description

Language tests are designed to assess an individual's receptive and expressive oral and written language skills in one or more of the following language domains: syntax (grammar/word order), morphology (words and word endings that add grammatical information to a sentence such as the past tense “ed”), semantics (vocabulary including words with multiple meanings as in “I’m feeling *blue* today”), and pragmatics (i.e., the social use of language). The purposes of language testing include (1) screening to determine if further and more comprehensive language assessment is needed; (2) diagnosis of a language disorder, impairment, or delay; (3) description of baseline functioning in one or more language domains; (4) development of individualized goals for language intervention; and (5) measurement of changes in language functioning in response to a language intervention. “[See Also](#)” below for a list of various language tests.

Psychometric Data

The design, development, and selection of a particular language test should account for the same considerations as other norm-referenced tests. In a norm-referenced language test, an individual's performance is compared with the performance of a representative group of people, referred to as a norm group or standardization sample. As such, the individual to be tested should be

represented within the norm group. Considerations for representativeness include similarities in age, grade level, gender, geographic region, ethnicity, language use (i.e., similar dialect or first language), and social economic status (usually determined by the individual's or the parent's educational and occupational levels). The size of the norm group should be large enough to ensure representativeness; most experts recommend that the norm group be comprised of at least 100 individuals in each age group (Sattler 2008).

Additional considerations for development and selection of a language test include reliability and validity. Reliability is the repeatability of a measure. Test-retest reliability assesses the repeatability of an individual's performance; that is, whether the individual performs similarly on the same test readministered within a short interval from the first administration (usually within a 1–2-week period). An equally important consideration is interjudge reliability. This type of reliability assesses whether two examiners would score the performance of the tested individual similarly so that an equivalent performance score is obtained.

The validity of a test refers to whether a test measures what it is proposed to measure. Validity must be considered for both test construction and test administration. Content validity refers to whether the items in the test represent the particular language domain being tested. For example, a test of syntactic skills should be comprised of a variety of sentence structure and forms, and the correctness of the response should be based on the use of the correct syntactic form rather than other aspects of the response. Face validity, a subjective judgment, refers to whether examiners and individuals receiving the test perceive the test as a reasonable measure. Construct validity is the degree to which a test measures a specific language construct. For example, higher scores on a language test should reflect a higher degree of skill level; similarly, lower scores should reflect a disorder, impairment, or delay in the language domain being tested. Concurrent validity reflects how well the test results agree with other tests that measure the same language domain.

In addition to the validity of the test construction, validity of the test administration must be considered by the examiner. An individual's test performance can be compromised by a variety of factors including fatigue, distractibility, anxiety, physical handicaps, hearing loss, educational opportunities (such that the child/adult has not been exposed to the same language stimulation as those of his/her peers), and familiarity with the test material. One limitation of most language tests published in the United States is that the tests do not include children and adults in the norm group who are learning English as a second language or who are being raised in a culturally different community than the mainstream community. This limitation precludes the validity of using language test scores to identify and diagnose language impairments in culturally and linguistically diverse children and adults. In any case, language tests should not be the only tool used to determine an individual's language performance (see next section for further discussion of this topic).

Clinical Uses

The most common purpose of language testing is to establish a diagnosis; language testing alone is usually not sufficient to identify intervention goals or to document intervention outcomes. Therefore, language testing is only one aspect of a comprehensive language assessment and evaluation. Language tests should be supplemented with descriptive developmental assessments, criterion-referenced procedures, language sampling, naturalistic observations, and caregiver/teacher report measures so that a complete profile of an individual's language performance across settings and communication partners is obtained.

Synonyms

[Interval](#); [Latent time](#); [Response time](#); [Time interval](#)

Definition

Latency is a type of continuous measurement used to measure behavior. Latency refers to the time from the onset of a stimulus, to the start of a response (i.e., behavior). Latency can be measured in seconds, minutes, or hours. Most commonly latency is represented in seconds or minutes. Latency is utilized as a measure for both adaptive and challenging behaviors.

Latency measures can provide important information about the impact an antecedent has on a behavior. Short latencies suggest a strong relationship between an antecedent and the behavior that follows it. Long latencies suggest a weaker relationship. Latency has been utilized in the assessment of behavior for individuals with Autism Spectrum Disorders (see “► [Functional Analysis](#)”) and may provide a more sensitive measure than other types of measurement (i.e., frequency or duration).

Definition

Latent variable modeling refers to a varied group of statistical procedures that use one or more unobserved (latent) variables to explain and explore relationships between a larger set of observed variables. There are many different types of analyses that fall under this general heading, but they can be generally grouped into four categories: models that assume one or more latent dimensions (exploratory and confirmatory factor analysis), one or more latent categories (latent class analysis, latent profile analysis), both latent categories and dimensions (factor mixture modeling), and structural models that enable us to examine relationships between latent variables.

Although not strictly latent models, taxometric procedures and cluster analyses also examine the question of whether observed data can be explained by one or more categories.

Together these procedures are useful for understanding: (1) how autism symptoms and related behaviors aggregate into dimensions; (2) the relationships between dimensions; (3) whether autism is qualitatively distinct from typical social and repetitive behavior; (4) the relative contributions of genetic, shared environment, and unique environmental factors to autism symptoms in behavioral genetics models; and (5) whether distinct subcategories of autism can be identified. The latter issue may be particularly important for identifying autism subgroups that more closely link to specific biological abnormalities or molecular etiologies.

Law Enforcement Agencies and Autism

David L. Holmes
Lifespan Services, Princeton, NJ, USA

Definition

Law enforcement agencies include local police, state police, federal bureaus of investigation, state

and federal courts, and all other law enforcement agencies responsible for the enforcement of laws pertaining to the safety, welfare, and security of a country's citizens.

Historical Background

In the United States, autism is on the rise with now approximately 1 in 88 children identified as being on the autism spectrum (Centers for Disease Control and Prevention [CDC] 2012).

With this significant increase in the number of individuals being diagnosed with autism, with individuals with autism spectrum engaging in almost all activities of daily life, and with entitlements and eligibilities through the Individuals with Disabilities Education Improvement Act (IDEIA) as well as civil rights laws including the Americans with Disabilities Act (ADA) and Section 504 of the Vocational Rehabilitation Act (1975), individuals with Autism, as with other developmentally disabled individuals, have a sevenfold increased probability of coming in contact with law enforcement agents than age-matched, nondisabled individuals (Curry et al. 1993).

Affirming this inclusion of people with autism spectrum as being part of the fabric of American society with all of its diversity and ethnicity, culture, gender, religion, sexuality, and disability is their recent inclusion in television, in books, in movies, and in Internet activities.

For example, books such as Jody Picoult's (2010) *House Rules* focus on a young teenage boy with autism who is obsessed with police activities and crime scene replications. This teenager with autism eventually becomes "a person of interest" in a murder in his small town merely because of his obsessive-compulsive interest in the case.

Another recent book by Mark Haddon (2003), *A Curious Incident of the Dog in the Night-Time*, also depicts a boy with autism and his engagement with law enforcement as he tries to unravel the death of his neighbor's dog; he too is a "person of interest" due to his peculiar behavior.

More recently, there are increased depictions of autism on television including "The Big Bang Theory," "Bones," and "Parenthood" (Seginwall 2010).

Movies are also depicting autism. The first such movie was the four Oscar Award winning "Rain Man" (1988) and, more recently, the seven Oscar Award winning movie "Temple Grandin" (2010).

The significant increase in the diagnosis of autism in the United States is reflective of increased awareness by the public, expansion of the diagnostic symptomatology, environmental issues, and more sensitive data (Centers for Disease Control and Prevention [CDC] 2011).

With autism being depicted in media, both print and video, as well as the significant increase in numbers of individuals being diagnosed with the syndrome, it would be expected that our federal, state, and local law enforcement agencies would have a better understanding of the disability and that their reason for existence, i.e., "to protect and serve," would in turn benefit those with autism spectrum disorder (ASD). Such an expectation is not usually the case.

Although law enforcement agencies are becoming more proactive in training their forces to be sensitive to the symptoms and responses by those on the spectrum when confronted by a law enforcement agent, individuals with autism spectrum are continuing to be misunderstood, both by law enforcement agencies as well as the courts (Debbaudt and Rothman 2001). To this end, individuals with autism are being seriously hurt and sometimes even die while in custody.

In Los Angeles, CA, a young man with autism was shot and killed by a police officer merely because he "did not respond to his directives"; he appeared to be "a shadowy figure" as he lay under a balcony behind an apartment building (Watkins 2011).

His mother stated, after the shooting, that he was merely "experimenting with living outdoors" as he was "fascinated by reading about homelessness."

In 2006, a teenager with autism in Miami is now "brain dead" after officers "hog-tied him following an outburst." He apparently suffered from a "lack of oxygen to his brain," anoxia (Local10.com 2006).

Situations like this are increasing in frequency across the nation due to poor or no training for law enforcement agents in how to identify individuals

on the autism spectrum and then how to engage them in order to protect not only the person with autism but also the law enforcement officer[s].

One individual who has pioneered the training of law enforcement officers in dealing with individuals on the autism spectrum is Dennis Debbaudt. He published a handout for law enforcement agencies entitled "Avoiding Unfortunate Situations" (2002). This handout is used in training law enforcement officers to be able to identify when they are dealing with an individual on the autism spectrum and then how to effectively interact with that individual in order to de-escalate the situation and to avoid harm to the individual and/or to the law enforcement agent.

Current Knowledge

Reasons for Law Enforcement Engagement

Before discussing how it is that law enforcement agents should respond to matters involving individuals with autism, it is important to describe what those matters may entail.

First, if a child with autism is self-injurious, parents can be accused of child neglect and abuse when neighbors, acquaintances, family members, school personnel, or medical personnel notice that a child has bruises, abrasions, and/or lacerations on his/her body. In the majority of such cases, law enforcement is contacted by school, medical, and/or social service personnel.

Sometimes, under such conditions, the child is taken into protective custody, leaving the parent to defend his/her reputation all the while mourning for the loss of their child to the situation – one which is unfamiliar to the parents and the child, leaving them anxious and frightened. More often than not such conditions are determined to be self-imposed in nature, and the child returned to his/her family; but the event itself is traumatizing to the parents as well as the child (Rzucidlo 2006).

Another reason for involvement of law enforcement agencies can be when a person with autism is creating "a public nuisance." Such behavior can be as innocent as entering a neighbor's home without permission, looking in the windows of a neighbor's home, or, more

seriously, making "terroristic threats," i.e., yelling epitaphs out of fear or anger, and/or public nudity to name a few.

Another reason for involvement might be failing to heed the directions of law enforcement agents when, for example, it comes to motor vehicle infractions. Failing to stay within the speed limit, come to a full stop at a stoplight, and even driving too slowly can be reasons for law enforcement to attempt to issue summonses.

Another area can be domestic violence, where an individual with autism may be assaulting his mother or father or siblings while having a behavioral meltdown or tantrum. This may include property damage as well.

Currently, an ever-increasing area where law enforcement comes in contact with autism is in illegal Internet activity including hacking into Web sites and databases and, even more devastating, viewing child pornography.

And finally, a disturbing trend that is developing across the United States is when personnel in service agencies responsible for individuals with autism call law enforcement agents when an individual with autism becomes "out of control." For many such NGOs (nongovernment organizations), this is a policy for "managing" behavior, one which is ill-conceived.

Rather than contacting law enforcement to manage such situations, NGOs should have internal policies and training for staff to be able to be the first responders to behavioral outbursts rather than relying on lesser-trained or untrained law enforcement agents to manage these highly volatile and potentially dangerous situations.

With the aforementioned examples in mind, it is apparent that a person with autism can either be the victim or the perpetrator requiring nuanced responding on the part of the law enforcement agencies responsible for the case.

Today, due to heightened potential for civil suits against law enforcement agents, we are finding that law enforcement agencies are concerned not only for the health and safety of all individuals involved in a case but also ensuring that their investigative and retention practices do not expose them to civil or criminal suits. They sometimes find themselves defendants for overreacting

and causing harm, unlawful seizure/retention, and wrongful death (Johnson 2007).

To this end, law enforcement agencies are putting forth a greater effort to properly train law enforcement agents in “tactical communication.” George Thompson, founder and president of the Verbal Judo Institute, Auburn, New York, metaphorically states it quite succinctly:

The American Eagle as shown on the dollar bill holds a spear in one talon and an olive branch in the other. This is the image of the peace warrior – what every police officer should also reflect, however most police training focuses only on the spear. Tactical communication training focuses on the olive branch. (Thompson and Jenkins 2004)

From what is known about individuals with autism, being able to “tactically communicate” with them always results in the best possible outcome not only for the individual with autism but also for the law enforcement agent.

Responses of Individuals with Autism

Research has demonstrated that the majority of individuals with autism have overly active amygdala, the centers of the brain that trigger a fight-or-flight condition (Baron-Cohen et al. 2000). The prefrontal cortex is the area of the brain for executive functioning; it helps to determine whether a condition/situation requires “fight or flight” or should be directed to the hippocampus, the area for calming and happy thoughts (Umeda et al. 2010).

For individuals with autism, the prefrontal cortex and hippocampus are often not as robust as in typical individuals, and so, the amygdala then is the ultimate arbiter of environmental engagements. As such, most individuals with autism are in a state of alertness/vigilance, and any stimulus that has a history of an attribution of trauma or fear on the part of the individual can trigger a significant behavioral response, one that appears to be “overreacting.” Novel experiences also have a tendency to trigger the amygdala and result in fear, anxiety, and panic on the part of the individual with autism (Holmes 2009).

With this in mind, when law enforcement agents engage an individual with autism, more

often than not, if improperly handled, such engagement can trigger a fight-or-flight response on the part of the individual usually resulting in someone getting hurt or worse, mortally wounded.

Future Directions

Information that Law Enforcement Agents Should Have

Individuals in law enforcement should understand that autism is a developmental disorder that severely impacts the capacity of an individual to understand social values and mores and also to comprehend language, especially language that is replete with sarcasm, idioms, and/or suggestion (The Autism Society of America 2011).

To these ends, training for law enforcement agents must focus on tactical communication, i.e., approaches that utilize proper language, e.g., language that is concrete and to the point, and directives that tell an individual *what to do* as opposed to merely *what not to do*.

Individuals with autism become anxious when they are told to stop doing something without being told what they can and should do under the circumstances. For example, telling an individual not to view child pornography without explaining the profound impact on children and the severe legal consequences for the behavior must be replaced with something more prosocial. He must be told the consequences of such behavior and given one or two clear choices to replace that immoral/illegal behavior (Moran et al. 2011).

It is important to note that more alternative choices rather than fewer is not necessarily indicated as it may create anxiety on the part of people with autism as choice making is a conflicting, difficult exercise for them.

Being aware of “body language” is also important as individuals with autism have difficulty reading nonverbal social cues such as facial emotions and body posturing.

In an article “Contact with Individuals with Autism” by Dennis Debbaudt and Darla Rothman published in the FBI Law Enforcement Bulletin (April, 2001), these authors review the many

nuances of autistic individuals' responses in general and specifically when law enforcement agencies are involved with them in order that agents would not feel that the person is dismissing them, mocking them, or resisting their directives.

Additionally, they address how an agent should interact with a person with autism in order to defuse and/or not incite an individual when responding to a crisis or investigating a potential criminal activity. Specifically, they discuss behavior that will help agents recognize persons with autism and then they offer suggested responses on the part of law enforcement agents in order to secure the safety of the person with autism as well as the safety of the law enforcement agent and others.

Recognizing a Person with Autism

A person with autism:

- Has difficulties with communication, maybe nonverbal, maybe echolalic, i.e., repeating exactly what is said to them (may appear as mocking), may utilize a communication system such as the Picture Exchange Communication System (Bondy and Frost 2001), may use a computer-generated augmentative communication system, and/or may use sign language.
- Has significant social challenges and may appear to ignore/dismiss the law enforcement agent.
- May not heed a request to "stop" by running away in a fight-or-flight response.
- Oftentimes has heightened levels of anxiety and may rock back and forth covering ears and moaning or screaming.
- May not recognize the law enforcement agent's badge or uniform or even understand the authority associated with such information.
- Usually only understands concrete information and will respond in a concrete manner. For example, (agent) "What are you doing?"; (person with autism) "Standing here."
- Does not understand sarcasm, jokes, or teasing.
- Generally presents poor eye contact or maladaptive eye movements appearing to be indifferent or lying to the person making requests.
- Often has difficulties in determining personal space, more often than not by moving away, i.e., standing at a great distance from the law enforcement agent or, in some cases, rapidly approaching the agent in an effort to hug or make personal contact with the agent.
- May appear argumentative or belligerent by not responding to demands of the law enforcement agent or constantly inquiring as to why demands are being made.
- May be extremely fearful of dogs (K-9 responders) and sights (flashing lights) and sounds (sirens) associated with law enforcement.
- May be on medication that makes the individual appear to be drunk or on drugs.
- May try to get the law enforcement agent to leave by screaming incessantly or attempting to bite or spit at the law enforcement agent.
- May bang his head against hard surfaces or generally engage in self-injurious or non-directed assaultiveness.
- May try and calm himself/herself by engaging in significant self-stimulatory behavior including hand flapping, head weaving, body rocking, and clapping hands.
- May have epileptic seizure activity including petit and grand mal seizures.
- May incessantly inquire of the law enforcement agent personal information in a perseverative fashion including "What is your name?" "How old are you?" "When were you born?," all of which may appear to be distracting the agent from his line of duty when in actuality he is merely collecting information to better know the agent.
- Will be correct/exact in responding, often agreeing to culpability at a crime scene or during interrogation in an effort to try and get back to some order in their life, as change and disruption in routine is very distressing.
- During interrogation, due to central auditory processing dysfunctions, may affirm portions of what they hear, as they are not able to process all the questioning and information presented to them. This frequently leaves the interrogating agents with testimony that holds individuals with autism accountable for behavior that they did not engage in.

How to Respond to an Individual with Autism

- Speak slowly and concretely; do not use slang or metaphors.
- Allow extra time for the individual to process information, sometimes a 3–5 s delay.
- Position oneself so as not to give the impression of blocking the individual, which may only trigger a fight-or-flight condition.
- Be a calming influence under volatile conditions as individuals with autism can sense fear, anger, and other emotions in others more readily than being able to see/read such emotions on others' faces and body language.
- Do not engage in interrogation activities until the situation is calm and the individual with autism appears safe and more relaxed.
- Ask caregiver/parents about a situation rather than expecting the person with autism to be able to answer questions with a high degree of fidelity.
- Assess the situation for any personal injury to the individual with autism frequently as they may be unaware of personal safety and danger as well as, due to lower sensory feedback mechanisms, lack awareness of physical injury to themselves.
- Due to sensory dysfunction, be aware of excessive lights and noises as this can result in a fight-or-flight response on the part of a person with autism.
- Move slowly with confidence as this will calm the individual with autism and reduce the potential for viewing the agent as a threat.
- Avoid touching the individual as this may be alerting and evoke a fight-or-flight response.
- Be prepared to use restraint procedures only as a last resort and always be aware of the potential for asphyxiation or bodily harm as a person with autism, under such conditions, frequently is in a heightened state of arousal and will be fighting the controlling measures. This can escalate to the point of agents compressing a person's chest and resulting in unintentional death.
- Finally, if a person with autism is required to be brought into custody, be certain to assess the capacities of the individual through consultation with a mental health/human services

professional who understands autism. Be prepared to segregate individuals with autism from the general population of those incarcerated as those with autism will be vulnerable to abuse and assault and do not have the capacity to defend themselves.

In conclusion, law enforcement, when autism is a consideration, requires ongoing in-service training of agents. Such training will help agents to better understand the motives behind the person with autism's behavior and, in turn, defuse what might otherwise be a situation that could result in someone getting hurt or even fatally harmed.

Law Enforcement Knowledge of Autism

Lauren Gardner
Child Development and Rehabilitation Center,
Johns Hopkins All Children's Hospital, Saint
Petersburg, FL, USA

Definition

This entry is focused on providing information regarding law enforcement officers' (LEO) knowledge of autism spectrum disorder (ASD). Little research exists on the number of interactions

LEOs have with individuals with ASD; however it is likely, given the current prevalence rates, that such interactions take place regularly. There are a growing number of training programs aimed at providing LEOs with the ability to recognize the presence of behaviors commonly associated with ASD. Through trainings that increase awareness and knowledge of ASD, it is hoped that LEOs are better prepared to respond in professional situations involving individuals on the spectrum.

Historical Background

Exposure of problematic interactions between law enforcement officers (LEOs) and individuals with ASD supports the need for ASD-specific training for LEOs. There have been a number of highly publicized encounters between individuals with ASD and LEOs that have resulted in injury to caregivers or the death of an individual with ASD. Copenhaver and Tewksbury (2019) completed an analysis of media reports involving LEOs and ASD to determine the types of interactions LEOs most commonly have with individuals with autism. Analyses yielded several themes including incidents involving autistic persons being questioned or treated as suspects, incidents where individuals with ASD were the victim of crime, wandering/missing persons with ASD, and positive stories of interactions between LEOs and individuals with ASD. As a result of previous incidents where LEOs were ill-prepared to respond to calls involving individuals with ASD, several US states including Florida, New Jersey, and Pennsylvania now require LEOs to receive training in ASD. Given ASD affects an estimated 1 in 59 individuals 8 years and older in the USA (CDC), it is likely that LEOs interact with individuals with ASD on a fairly regular basis. Lack of knowledge of ASD may result in LEOs misinterpreting ASD-specific behavior as non-compliant, threatening, disorderly, or suspicious.

Interactions among LEOs and individuals with ASD may result from a variety of circumstances. Encounters may include individuals with ASD presenting as a victim or witness to crime; the individual may be suspected of committing a

crime or may have wandered away/gone missing. Previous research documents that persons with developmental delays, including those with ASD, are at increased risk for abuse and victimization (Petersilia 2001). In other instances, interactions between LEOs and individuals with ASD may be as a result of co-occurring psychiatric or medical concerns (Tint et al. 2017). LEOs may also be called upon in cases involving elopement, sensory overstimulation, and behavioral difficulties such as aggression, yelling, and self-injury. Using a nationally representative sample of adolescents and young adults with ASD, Rava et al. (2017) found that by age 21 approximately 20% had been stopped by the police for questioning, and almost 5% had been arrested. Rava et al. (2017) also found that individuals with ASD who display externalizing behaviors are more likely to be involved in the criminal justice system. Previous research offers conflicting findings as to whether children and young adults with ASD are at higher risk for involvement with the criminal justice system than the general population; however, it appears likely based on existing research that people with ASD are somewhat over-represented in the criminal justice system (King and Murphy 2014). As LEOs are the first contact between individuals and the penal system, instruction for LEOs specific to ASD is warranted. Such training provides LEOs with awareness of the behavioral symptoms and social impairments that may make an individual with ASD more vulnerable to be considered a suspect. For example, if an individual with ASD does not respond to police when spoken to, avoids eye contact upon questioning, does not remain still or tries to flee the scene, these behaviors may be misinterpreted as a sign of guilt as opposed to behavioral characteristics of ASD. Although in the UK it has been suggested that officers ask the question “Do you have any difficulties that I may not be aware of?” during initial contact with a person they suspect may have autism, individuals with ASD may not self-disclose their diagnosis to LEOs due to fear of discrimination (Crane et al. 2016) or due to communication/language delays and deficits associated with their ASD diagnosis. Murrie et al. (2002) noted that failure to correctly identify

individuals who are on the autism spectrum, or overlooking the behavioral features characteristic of an ASD diagnosis, may lead to inappropriate forensic assessment of criminal responsibility, legal decisions, or clinical interventions.

Current Knowledge

Research regarding LEO knowledge of ASD and disability awareness is sparse. A study by Modell and Mak (2008) found that 80% of officers were unable to accurately identify characteristics of ASD, had difficulty distinguishing between disabilities, and perceived themselves as competent in ASD when they may not have been. In a study of UK officers’ awareness and understanding of autism, Chown (2009) found that 62% of officers had received no formal training in ASD, and approximately half were able to recognize key features of autism. Although officers in the Chown study rated their competency in ASD lower than officers in the Modell and Mak study, findings suggest officers’ self-assessments may exaggerate competence. Research findings support that the majority of LEOs receive very little or no training in disabilities and ASD (Chown 2009; Eadens et al. 2016). As such, it is not surprising that they demonstrate limited knowledge of the characteristics of ASD and how to appropriately respond to incidents involving individuals with ASD.

Several studies have been conducted examining LEO training requirements and inclusion of training specific to ASD. Laan et al. (2013) conducted interviews with LEO training coordinators in seven states and compared LEO training materials related to recommendations for training on ASD and guidelines for training on other mental health disorders. Results indicated that most officers received between 400 and 770 hours of total training at the basic recruit level, of which only 3 to 12 hours were focused on mental health disorders. Training provided on mental health disorders that includes ASD is problematic as autism is not a mental health disorder. Although individuals with autism may present with co-occurring mental health diagnoses, providing training that

presents ASD as a mental health disorder to officers may result in confusion and impair LEOs' ability to accurately distinguish autism from other mental health disorders (Hepworth 2017). Gardner et al. (2019) found that although over half of LEOs reported having responded to a call involving an individual with ASD within the last year, over 70% of officers reported they had received no formal training in ASD. A quarter of these calls resulted in involuntary psychiatric hospitalization of the person with ASD. Although some states, such as Florida, New Jersey, and Pennsylvania have now mandated ASD training for LEOs, little is known regarding training content, format, or the impact of these trainings on practice. In addition, extension of this training requirement to other states and inclusion of other first responder departments (e.g., firefighters, EMS, etc.) remains unknown.

Research findings indicate that LEOs who have completed ASD-specific training report they feel better prepared to respond to incidents involving individuals with ASD (Gardner et al. 2019). A study of LEOs' perception of the most positive aspects of ASD-specific training included increased general knowledge of ASD, minimizing distress of individuals with ASD when responding to a call, practical application and usefulness for their LEO role, and modifying interview techniques. The top three aspects of training that LEOs deemed not satisfactory included training that lacked focus on ASD in the criminal justice context, overly simplistic content, and lack of practical application and relevance for LEOs (Crane et al. 2016). Chown (2009) police survey respondents suggested training should be streamlined into existing training programs, utilize a variety of delivery mechanisms as people learn best in different ways, include a variety of disabilities, incorporate advice on tactics to use, provide opportunities to interact with persons with ASD, and provide specific questions officers can ask to someone to determine if they have a hidden disability.

In considering the ideal format for increasing LEO awareness of ASD, in-person training is considered superior to online training modules.

Teagardin et al. (2012) provided ASD-related training to police officers via video. Officers who participated in the training outperformed officers who did not receive training on a measure of ASD-related knowledge; however, neither group demonstrated mastery of training material. The authors concluded that video training is likely insufficient to train officers on how to assess and respond to individuals with ASD. Instead of video or online training, in vivo training provided by individuals who have expertise in ASD and law enforcement is ideal as it increases the validity of the ASD training. It is recommended that in vivo training includes opportunities for role-playing and hands-on activities to supplement training. As a vulnerable population within our society, a growing awareness of ASD by LEOs is warranted; however, LEOs' experiences and knowledge specific to ASD remains an under-researched area.

Future Directions

Additional research is needed to determine the ideal format for training to increase LEOs' knowledge of ASD and prepare them for contact they may have with individuals with ASD in the course of their duties as an officer. In addition, further research is needed to determine the most pertinent and appropriate content to provide LEOs about ASD. Previous research suggests trainings should include information regarding the core features of autism, as well as practical knowledge and specific tactics for interacting with autistic persons. More information is needed regarding the types of calls LEOs receive in the line of duty that include individuals with ASD (e.g., missing person, victims of abuse, domestic assault, etc.) to assure that training programs provide information that is most applicable for LEOs.

As the reported prevalence rate of ASD increases, LEOs are increasingly more likely to interact with individuals with ASD within their professional role on a regular basis. Results of previous research supports there is a need for LEOs to receive formalized training in ASD

(Chown 2009; Eadens et al. 2016; Gardner et al. 2019; Modell and Mak 2008; Teagardin et al. 2012). Outcomes of such trainings result in LEOs reporting they feel better equipped to respond to calls involving individuals with ASD (Gardner et al. 2019). However, research is needed to determine the real-world impact of ASD-specific training on outcomes of calls (e.g., use of force, arrest, involuntary psychiatric hospitalization), especially given previous findings that LEOs tend to perceive themselves as competent in ASD when they may not be (Modell and Mak 2008; Chown 2009).

Lawson, Wendy

Adam Feinstein
Autism Cymru and Looking Up, London, UK

Name and Degrees

Dr. Wendy Lawson (Bss, Bsw [Hons], GDip [PsychStud], GDip [Psych]) is an Australian writer, poet, adult educator, and immensely popular public speaker with Asperger's syndrome. In 2009, she was awarded her Ph.D. in Psychology at Deakin University in Victoria, Australia. Her work explores the influence of neurologically

typical development on that of development in individuals with autism and its impact upon learning styles and related parental distress. Dr. Lawson has been married, separated, and divorced. She brought up four children and has experienced the death of one of her teenage sons. Wendy's younger son, Tim, also has Asperger's syndrome. She has said: "I knew Tim was like me in so many ways. He has a big heart and a wide appealing grin. Seeing him experiencing similar difficulties to my own, though, is painful and I so wish I could make life easier for him."

At school, Wendy was considered to be intellectually disabled and "almost incapable of doing as she is told." In her teens, she was misdiagnosed as "schizophrenic." This label stuck for more than 25 years, until she was diagnosed in 1994 as being on the autism spectrum. She coined the term "diffability" to refer to her view that high-functioning autism is as akin to a difference as to a disability.

In 2008, Dr. Lawson was awarded fourth place as "Victorian Australian of the Year."

Lead Exposure and Autism

Lisa Wiesner

Pediatric and Adolescent Medicine, Orange, CT, USA

Synonyms

[Lead poisoning](#); [Plumbism](#)

Definition

Lead exposure results when an individual is exposed to this heavy metal. Lead is toxic to a range of organ systems and is particularly problematic in children where it can interfere with development and lead to a range of problems in behavior and in learning. Physical symptoms such as abdominal pain, irritability and confusion, and anemia can be noted, and with high levels of lead, seizures and even death can result. Lead can be taken into the body through contaminated food, water, and the air. Lead paint has been the most frequent source of exposure in the past (fortunately this is now decreasing because of public health awareness and new standards for paint and other materials) but can still arise in older homes. Prevention is important. Children, e.g., those with autism, who frequently mouthed objects can be at higher risk.

At lower levels of lead exposure, children have few problems although even then subtle problems may exist. The Center for Disease Control and Prevention considers any lead level of 10 µg/dl or above to be abnormal. A level of lead above this level should lead parents/caretakers to search for sources of exposure. At levels of 40 µg/dl or above, anemia may be noted, with high level (60 µg/dl) resulting in developmental and behavioral change and even brain symptoms (coma or seizure).

Primary care providers should routinely screen for lead exposure in younger children and even in older children who may be at risk because of possible exposure, e.g., through repeated

LDS

► [Language Development Survey](#)

mouthings of objects. Clearly removal of sources of exposure is important. A range of medications are available to lower levels of lead through chelation (chemicals that bind with lead so that it is excreted from the body). These agents do have some risks and side effects, and treatment should be carefully managed by a physician.

Leaky Gut Syndrome

Kimberly Johnson
Neurodevelopmental and Behavioral Pediatrics,
Children's Hospital Colorado, Aurora, CO, USA

Definition

Autism spectrum disorders (ASD) comprise a group of diagnoses that are collectively characterized by qualitative impairments in social interaction and communication along with stereotyped and repetitive behaviors and interests. The underlying cause, or etiology, of ASD is poorly

understood but may be multifactorial with both genetic and environmental factors playing a role. The “leaky gut syndrome,” as it applies to ASD, is based on the theory that the lining, or mucosa, of the intestinal wall is damaged, allowing the contents of the intestine, such as undigested food, toxins, bacteria, and waste, to “leak through” an abnormally permeable bowel wall. There are many theories involving the leaky gut, or increased intestinal permeability specific to ASD. One of these is the leaky gut-opioid excess theory, which posits that incompletely digested proteins derived from the diet are absorbed through a leaky gut, thereby entering the central nervous system and interfering with normal brain function which may cause or exacerbate the behavioral symptomatology of ASD (White 2003).

Historical Background

Many parents of children with ASD report concerns with gastrointestinal symptoms. Associated behavioral symptoms, including behavioral disruption at mealtimes, unusual vocalizations, sleep disruption, and irritability, could be secondary to gastrointestinal distress (Buie et al. 2010). There have also been observations of gastrointestinal symptoms coinciding with the onset of parental concerns regarding development. The hypothesis of a “gut-brain linkage” in ASD is based in part on these reports (White 2003). The suggestion of potential links between celiac disease (a digestive condition triggered by consumption of the protein gluten found in wheat, barley, and rye) and malabsorption in ASD arose in early research conducted in the 1960s and 1970s (Horvath and Perman 2002). This was followed by relatively little investigation into the possibility of gastrointestinal abnormalities in autism until the 1990s when research positing a difference in the immune function and permeability of the gut was published (Erickson et al. 2005). Since that time, exploration of gastrointestinal differences and their association with ASDs has continued, along with debate regarding whether gastrointestinal symptoms are truly more prevalent than in

the general population and whether there is an autism-specific gastrointestinal abnormality (Buie et al. 2010).

The leaky gut-opioid excess theory involves peptides derived from the partial digestion of gluten (a protein found in wheat, barley, and rye) and casein (a protein found in milk), specifically gliadomorphins and casomorphins respectively, being absorbed through a leaky gut and entering the central nervous system (de Magistris et al. 2010; Millward et al. 2009). The theory hypothesizes that these peptides, referred to as exorphins due to their dietary origin, mimic the opioid hormone β -endorphin and interfere with normal brain function. This theory was based in part on a concept posited by Panksepp in 1979 that the behavioral symptomatology of autism may be secondary to increased activity of the opiate system. The concept was based on work performed in young animals. These animals showed symptoms similar to those seen in children with ASD when they were given low doses of opiate drugs (Christison and Ivany 2006; Panksepp 1979). Subsequently, Dohan developed a hypothesis regarding an excess of dietary peptides from gluten and casein interacting with a genetic disposition in the etiology of schizophrenia. This hypothesis was based in part on anecdotal reports of increased incidence of celiac disease in schizophrenia and the decreased prevalence of schizophrenia in populations that consumed little to no grain products (Dohan 1988). Meanwhile, people with ASD were reported to show an increase in 24-h low molecular weight peptide excretion in their urine (Cass et al. 2008). Increased opioid levels were also reported in the cerebrospinal fluid of individuals with ASD (Millward et al. 2009; White 2003). Clinical trials of opiate antagonists in the treatment of ASD followed. Researchers proposed dietary elimination of these proteins as a potential treatment for ASD. Anecdotal reports of this dietary intervention noted improvements in symptoms of ASD (Christison and Ivany 2006). To date, the gluten-free, casein-free diet is a popular but yet unproven intervention in ASD (Buie et al. 2010).

In order for these peptides to be abnormally absorbed, there would have to be evidence of

increased intestinal permeability or a “leaky gut.” In the healthy gut, the intestinal mucosa serves as a barrier against the largest site of exposure to the external environment in the human body. The integrity of this barrier is important to protect the body against bacteria, toxins, or antigenic molecules (a substance that can trigger the production of antibodies by the immune system). A layer of epithelial cells serve as this physical barrier. Underlying this barrier is the highly immunoreactive subepithelium, which serves as a line of defense to invading organisms that breach the epithelium. Breaching the epithelial barrier can lead to pathologic stimulation of the subepithelium by exposing it to the numerous antigenic molecules, including food antigens, located in the lumen of the intestine. Intestinal permeability has been associated with several medical conditions, including celiac disease, inflammatory bowel disease, diabetes mellitus type 1, and atopic disorders such as allergies, eczema, and asthma (Liu et al. 2005). Intestinal permeability is often tested through the differential sugar absorption test. This test involves the ingestion of two indigestible sugars of different molecular sizes and absorption routes, which are secreted in the urine after uptake from the gastrointestinal tract, typically lactulose and mannitol. In the healthy gut, absorption of the larger sugar lactulose is much less than for the smaller sugar mannitol. In pathologic conditions, the permeability for the larger sugars is increased while that for the smaller sugars remains the same or decreases (D’Eufemia et al. 1996; de Magistris et al. 2010; Liu et al. 2005). Therefore, the ratio of the large (lactulose) to small (mannitol) sugar is increased. This has been the method for assessing intestinal permeability in children with autism spectrum disorders. D’Eufemia et al. (1996) performed early work on this topic. They evaluated 21 children with autism who were without gastrointestinal symptoms and 40 healthy, age-matched controls. Nine of the 21 children with autism had an altered lactulose to mannitol ratio compared to none of the controls. The researchers noted that mannitol passes through the gut wall via a trans-cellular pathway. Lactulose, however, passes through the gut wall via intercellular routes as do

other heavier compounds, including peptides. They hypothesized that the increased permeability may be secondary to damage to the tight intercellular junctions of the gut mucosa. These tight intercellular junctions connect the epithelial cells to their neighbors and limit movement of molecules between the cells (Liu et al. 2005).

Although the possible mechanisms are unknown, multiple hypotheses have been suggested regarding the potential cause of increased intestinal permeability in individuals with ASD (White 2003). Gut inflammation may lead to increased permeability as well as diminished digestive enzyme activity including that of peptidases (enzymes that break down proteins), which may account for the incompletely digested peptides. Conversely, the loss of integrity of the gut mucosa could lead to pathologic stimulation of the immune system given the increased exposure of immunogenic compounds (Liu et al. 2005; White 2003). Inflammatory responses in the gut of children with ASD have been reported (Erickson et al. 2005; Horvath and Perman 2002). Intestinal pathology described by Wakefield et al. (2005) included ileal lymphoid nodular hyperplasia and nonspecific colitis in children with autism spectrum disorders. The possibility of an autism-specific gastrointestinal abnormality, referred to as “autistic enterocolitis,” has often been cited as a potential link in the chain of the “leaky gut” hypothesis (Buie et al. 2010; Erickson et al. 2005; Wakefield et al. 2005; White 2003). An environmental trigger, namely, the MMR (measles, mumps, rubella) vaccine, was suggested but never proven as a potential cause of the pathology in this hypothesis (Christison and Ivany 2006; Erickson et al. 2005; White 2003). Inflammatory responses are further thought to regulate the sulfated glycosaminoglycans (GAGs), which are widely distributed in the vascular and connective tissues of the healthy intestine. Decreased sulfated GAGs have been found in patients with inflammatory bowel disease, a finding which has been hypothesized to allow protein and fluid leakage across the wall of the intestine. Sulfation defects have been noted in children with ASD and could be one potential cause of increased intestinal permeability

(Erickson et al. 2005; White 2003). Further, ingestion of gluten itself has been linked with intestinal permeability as the protein component gliadin has been demonstrated to disrupt intercellular junctions (Liu et al. 2005). A genetic factor has also been implicated in impaired gut integrity in individuals by the finding of increased intestinal permeability in first-degree relatives of patients with inflammatory bowel disease (de Magistris et al. 2010; Liu et al. 2005). Further, a mutation affecting the expression of the gene encoding the MET receptor tyrosine kinase has been associated with both ASD and gastrointestinal conditions and functions in both brain development and gastrointestinal repair by modulating intestinal epithelial cell proliferation (Campbell et al. 2009).

Current Knowledge

Increased intestinal permeability has been linked to several hypotheses regarding the etiology or symptomatology of ASD, including immune dysfunction and increased opiate activity (White 2003). Intestinal permeability was initially reported by D'Eufemia et al. in 1996 on a small sample of children with autism spectrum disorders without gastrointestinal symptoms. This finding was not observed in healthy, typically developing controls. Overall, the literature is mixed in regard to the presence of a “leaky gut.” Two additional studies utilizing neurotypical controls were performed. The first study enrolled 14 children with ASD who had current or previous gastrointestinal symptoms by parental report, 7 unaffected siblings of these children, and 8 unrelated children with typical development. There were no differences detected on the differential sugar absorption test using lactulose and mannitol, as described above (Robertson et al. 2008). However, a recent study of 90 children with ASD and 146 of their first-degree relatives found that 37% and 21%, respectively, had increased intestinal permeability based on the differential sugar absorption test using lactulose and mannitol, compared to 5% of 146 healthy adults and none of the 64 healthy child controls. Remarkably, increased intestinal permeability was not associated with intestinal

inflammation when measured by fecal calprotectin in this study. Calprotectin is a protein in the intracellular fluid of neutrophils, which has been used as a noninvasive marker of inflammation in inflammatory bowel disease (de Magistris et al. 2010). These findings suggest that altered intestinal permeability may be a real finding in autism but may not be linked to intestinal inflammation.

Concern regarding an interactional relationship between factors affecting the functioning of the gastrointestinal system and that of the central nervous system underlying the etiology of ASD is based in part on reports of increased gastrointestinal dysfunction in children with autism spectrum disorders. To date, there is no conclusive evidence that the prevalence of gastrointestinal disturbance is elevated in individuals with autism above the general population. The reports of prevalence range from 9%, similar to the typical population, to 84%, most likely secondary to variations in methodology (Buie et al. 2010). Two recent studies again show mixed results. One recent population-based study examined the medical records of children with ASD and age/gender-matched controls using data from the Rochester Epidemiology Project, which captures detailed medical charts from more than 95% of the residents of Olmsted County, Minnesota. Their findings indicate that the overall cumulative incidence of gastrointestinal symptoms in children with ASD was not increased above controls, although there was a statistically significant increase in the cumulative incidence of constipation and feeding selectivity in children with ASD above controls. It is unclear whether the increase in constipation and food selectivity was due to gastrointestinal or neurobehavioral differences. The retrospective nature of data collection, with data being collected from medical records completed in the past, and the homogeneity of the racial and ethnic composition of Olmsted County (i.e., 98% of the population is reported to be white) limit the findings (Ibrahim et al. 2009). Another recent study is the only report to date to examine gastrointestinal problems in children with autism spectrum disorders from families with multiple affected members. Via a structured medical history interview,

data regarding gastrointestinal problems was collected on 589 children with ASD, verified by gold standard measures, and 163 sibling controls from 313 families. The authors found increased parental report of gastrointestinal problems in children diagnosed with an autism spectrum disorder (42%) versus their unaffected siblings (12%), with chronic diarrhea and constipation the most frequently reported. Inclusion of a novel severity ranking scale revealed increased odds of gastrointestinal problems with increased severity of ASD symptoms, a finding that will require replication. The retrospective nature of the data collection, largely relying on recall, limited the findings. Similarly, the inclusion of unaffected siblings may have introduced an additional bias as the children with ASD may have had increased medical visits and scrutiny leading to an increased identification of symptoms over their typically developing siblings (Wang et al. 2011).

The specificity of the endoscopic and histologic findings in the intestine, namely, ileal lymphoid nodular hyperplasia (LNH), to autism has been controversial, particularly as LNH has been noted in typically developing children with constipation and food allergy (Buie et al. 2010; Erickson et al. 2005). Other methodological concerns, including inappropriate control groups and lack of validated definitions, make the findings difficult to interpret (Buie et al. 2010). The connection between autism and the MMR vaccination has since been disproven (Hornig et al. 2008). The original article describing the endoscopic and histologic findings and the temporal relationship of the onset of symptoms of autism to injection of the MMR vaccine has now been retracted due to false claims regarding how the study was conducted (Harris 2010; Wakefield et al. 2010). Although inflammation of the gastrointestinal tract has been noted in children with autism spectrum disorders (Erickson et al. 2005; Horvath and Perman 2002), an autism-specific abnormality has not been established (Buie et al. 2010).

There is also conflicting evidence regarding the opiate excess theory. Studies examining the presence of excess opioid-like compounds in the cerebrospinal fluid and urine of individuals with ASD have revealed no consistent patterns (Cass et al.

2008; Ibrahim et al. 2009; White 2003). The clinical trials examining the efficacy of opiate antagonists in the treatment of ASD reported, at most, small benefit, principally in hyperactivity and self-injurious behaviors (Christison and Ivany 2006; Horvath and Perman 2002). Further, dietary elimination studies of gluten and casein showed mixed results. To date, there are only a few published randomized control trials (which are the most reliable form of scientific evidence in intervention studies) of gluten and casein elimination diets. The results are mixed with some general improvements noted on the diet in two of the three studies. However, methodological issues render the results difficult to interpret (Millward et al. 2009; Whitley et al. 2010). One small study was presented at the International Meeting for Autism Research in 2010 and reported on wheat and milk challenges in children with ASD placed on a gluten and casein elimination diet, finding no significant difference in outcome measures. While this was a randomized, blinded trial, the sample size was small (Hyman et al. 2010). Consequently, there is no current clear evidence on whether the gluten-free, casein-free diet is effective in ameliorating symptoms of ASD.

Research regarding a genetic predisposition involved in increased intestinal permeability in individuals with ASD is still preliminary. A recent study extended the findings of increased intestinal permeability to first-degree relatives of individuals with ASD, implying a genetic factor may be involved (de Magistris et al. 2010). The work regarding the gene encoding the MET receptor tyrosine kinase may imply that genetic factors contribute separately to gastrointestinal and neurobehavioral symptoms in individuals with ASD (Campbell et al. 2009). However, additional studies are needed before any firm conclusions can be made.

In conclusion, increased intestinal permeability has been documented in certain medical conditions such as inflammatory bowel disease and celiac disease. It has been hypothesized to play a role in psychiatric disorders such as schizophrenia. Further, intestinal permeability has been reported to be increased in children with autism spectrum disorders leading to etiologic theories,

including the leaky gut-opioid excess theory. To date, there is preliminary supportive evidence for altered intestinal permeability in children with autism spectrum disorders. Conclusions regarding whether this potential difference plays a role in the gut-brain axis and is therefore either causative of autism spectrum disorders or increases symptoms of ASD cannot be made. At this time, there is very little data to support the opioid excess theory or a gastrointestinal pathology specific to ASD.

Future Directions

Large prospective studies with appropriate control groups that take into account factors such as dietary intake and comorbid psychiatric conditions (e.g., anxiety and depression), which may play a role in functional gastrointestinal problems, are needed to further characterize gastrointestinal differences in children with ASD. Research targeting potential interventions in autism spectrum disorders need to encompass large, properly controlled trials with well-defined outcome measures. It is also important that researchers studying gastrointestinal abnormalities and intestinal permeability adequately characterize the sample with appropriate autism diagnostic measures. Given the heterogeneity of ASD, describing the subjects in terms of both gastrointestinal symptoms/disorders using standardized definitions and the developmental/behavioral phenotype may shed light on the difference between children with and without altered intestinal permeability.

Learned Helplessness

Peter Doehring

Foundations Behavioral Health, Doylestown, PA, USA

ASD Roadmap, Chadds Ford, PA, USA

Definition

A state in which animals and humans act as if events are outside of their control, and so do not try to escape from unpleasant conditions that they could otherwise easily avoid. This state is created by being repeatedly exposed to an aversive stimulus from which escape is impossible, and this state is then generalized to other stimuli. It is believed to contribute to depression and other related conditions.

Historical Background

The phenomenon of learned helplessness was described following a series of experiments led by Seligman and his colleagues beginning in 1967, first involving dogs and rats (Seligman 1968), and then involving humans (Miller and Seligman 1973). In humans, learned helplessness was manifested as a perception that events were outside of the individual's control. This characterization of depressions was central to interventions which subsequently focused on changing cognitions surrounding the individual's perception of themselves, their actions, and the future. A database search of the key terms "autism" and "learned helplessness" revealed very few references to both terms, and so we have integrated past and present discussions related to autism and developmental disabilities under "[Current Knowledge](#)."

Current Knowledge

Learned helplessness was first discussed more extensively in the peer-reviewed literature on ASD when speaking to the challenge of motivating children exposed to repeated failure. Behavior analysts had postulated that the increased opportunity to access reinforcement that results from correct completion of a task should motivate the child to devote increased effort to completing other tasks. Koegel and Egel (1979) provided perhaps the earliest and most specific test of this hypothesis. They examined the level of interest and persistence evident in three young children with autism when presented with a series of fine motor tasks. Using a multiple baseline design, performance was compared under conditions of no prompts (pretreatment condition) and verbal and gestural prompts (treatment condition). During the pretreatment condition, children had low levels of task completion and interest, and decreasing attempts over time. In contrast, during posttreatment conditions, when prompting levels were comparable to pretreatment conditions, two of the three children demonstrated sustained improvements in interest and in the number of

attempts relative to pretreatment levels. Subsequent trials and conditions for the third child revealed that these improvements were only evident when he was successful at least 50% of the time; otherwise, attempts dropped dramatically in frequency. The authors framed these findings as demonstrating learned helplessness: Low rates of success masked the potential relationship between effort and outcome or, in behavioral terms, between response and reinforcement. Creating conditions for success made the response-reinforcement relationship more salient, and thus made children more likely to persist when initially unsuccessful. The potential disconnection between response and reinforcement was striking for the third child, for whom high levels of reinforcement were at times almost unrelated to effort. As the oldest of the three participants, he was the most likely to have experienced learned helplessness.

The Koegels returned to the role of learned helplessness at later points (Koegel and Mentis 1985). They suggested that teaching self-management skills to persons with ASD and other disabilities may help them to better understand the relationship between their own behavior and outcomes, and inoculating them against learned helplessness (Koegel et al. 1995). They also postulated that learned helplessness was central to understanding the potential effectiveness of pivotal response training or PRT (Koegel et al. 2001): "pivotal response interventions that emphasize relations between social communicative responses and their positive consequences appears to increase motivation to respond, thereby improving responsivity and increasing favorable environmental and social stimulation and interaction." (Koegel et al. 2001, p. 21). Learned helplessness may be a natural outcome of other difficulties faced by children with autism (e.g., the difficulty processing complex stimuli) within the first 18 months of life. Instead of seeking to initiate interactions with the environment, fueled by a response-reinforcer relationship growing in strength with each success, children with autism withdraw, effectively decreasing the number and type of learning opportunities available to them. The potential for disruption of the

response-reinforcer relationship may be particularly evident with respect to the deficits in social communicative interactions that are a hallmark of autism. The social and communicative exchanges that naturally emerge in exchanges between typical toddlers and adults (i.e., in the form of requesting, joint attention, social play, and other socio-affective interactions, etc.) simply do not occur in many children with autism or, if they do, only emerge later in development and at much lower rates. By the time autism is identified and intervention begins, the lack of persistence in the face of failure has already had a cascading effect on the number and type of learning opportunities available to the child with autism, especially with respect to social communicative interactions. Yet, just as learned helplessness can disempower the young child with autism, PRT can function (among other things) to reestablish the response-reinforcer relationship. The emphasis in PRT on self-initiation and self-management, on adaptations to help children respond to multiple cues and on the increase in motivation more generally, has an impact on the specific skills being taught, and on the child's perception of themselves as an effective agent in their interactions with their environment.

Learned helplessness has also been discussed in the context of depression and ASD. Barnhill and Myles (2001) found the same relationship between attributional style and depression among adolescents with Asperger syndrome, as is evident in other populations, namely, that depression is associated with a style in which the person blames themselves for negative events and outcomes, across contexts and time. These authors also suggested that positive behavior supports, which emphasize proactive interventions to prevent errors, may help to counter this negative attributional style.

Future Directions

At present, it is unclear how the relationship between learned helplessness and autism will be considered by future researchers and clinicians. The recognition of PRT as an evidence-based

practice, and of depression as an area of concern for adolescents and adults with ASD, suggests that an interest in learned helplessness may be rekindled among researchers and clinicians seeking to help all persons affected by ASD. Researchers and clinicians may also consider revisiting early research suggesting that learned helplessness is related to intellectual disability (Weisz 1979), and may be influenced by adult expectations and feedback (Raber and Weisz 1981; Weisz 1981).

Learning Disabilities

► Learning Disorders

Learning Disability

Patricia Prelock

Communication Sciences and Disorders, Dean's Office, College of Nursing and Health Sciences, Burlington, VT, USA

Synonyms

Language-based learning disability; Learning disorder; Specific learning disability; Specific learning disorder

Short Description or Definition

Learning disability is a term used to describe a heterogeneous group of disorders characterized by significant challenges in acquiring and using listening, speaking, reading, writing, reasoning, and/or mathematical abilities. A learning disability is considered intrinsic to the individual and is related to underlying neurological differences. Although it can co-occur with other disabilities and can be affected by environmental influences, it is not the direct result of these conditions or influences. The National Joint Committee on Learning Disability (NJCLD) has also used the term to represent the discrepancy that might exist between an individual's capacity to learn and their actual achievement level (National Research Center on Learning Disability 2010). Children with learning

disabilities have unique educational needs because they approach learning in different ways. Learning disabilities often have a language basis, and some children may be identified as having a language-based learning disability (Sun and Wallach 2014).

The term learning disability is not used in the DSM-5 (American Psychiatric Association [APA] 2013). Instead, specific learning disorders is the term used to characterize challenges in the acquisition and use of one or more areas of academic performance. These challenges must persist for at least 6 months whether or not intervention has been provided. Considering the most recent research, the DSM-5 expands the definition somewhat to account for persistent difficulties in reading, writing, arithmetic, and/or mathematical reasoning during formal schooling. Children with specific learning disorders are likely to approach reading in a slow and effortful manner with frequent inaccuracies (APA 2013; National Center for Learning Disabilities 2014). Their ability to understand what they read might also be compromised. Writing lacks clarity and organization, while solving mathematical problems and remembering number facts are difficult. Academic skills fall well below the expected level for a child's chronological age and cannot be explained by other developmental, neurological, vision, hearing, or motor disorders (APA 2013; NCLD 2014).

Categorization

There are several descriptions of the varying categories and classifications of learning disabilities. Learning disabilities are often grouped by an area of skill or cognitive weakness and are typically the result of challenges in the ability to process information in spite of intelligence in the average or above average range. Information processing is critical to learning and requires an ability to take in and decode information (input), integrate that information into what a person already knows or is experiencing, storing that information so it can be easily retrieved to facilitate future understanding, and encoding a response (output). Potential

Learning Disability, Table 1 Information processing challenges for individuals with learning disabilities

Levels of information processing	Learning issues for individuals with learning disabilities
Input level	Difficulty with visual perception causing recognition problems
	Sequencing challenges affecting temporal processing
	Challenges in auditory perception impacting ability to determine the relevance of auditory stimuli
	Problems processing tactile information
Integration level	Difficulty telling a story in sequence
	Problems remembering rote information like days of the week
	Challenges in generalizing new learning
	Problems with comprehension
Storage level	Problems with short- and long-term memory or working memory challenging new learning
	Difficulty with visual memory affecting spelling
Output level	Challenges in the formulation of words, gestures, writing, or drawing
	Difficulty with spoken language including answering questions on demand, retrieving vocabulary, organizing thoughts prior to speaking or writing
	Problems with motor output affects written language, physical activity (e.g., riding a bicycle), and daily living or self-help skills (e.g., tying shoes)

challenges in each of these four areas that affect learning are summarized in Table 1.

The DSM-IV-TR and the DSM-5 (APA 2000, 2013) specifically identify three disorder areas that would be considered under the category of learning disabilities or learning disorders (see Table 2 for a description). A diagnosis in any one or more of these categories would qualify a student for support indicating they cannot access, interpret, and formulate learning in an expected manner. The DSM-5 (APA 2013) also describes three severity levels (mild, moderate, severe) for children with learning disorders, highlighting likely difficulties and the level of intervention support required.

Although not part of the learning disorders described in the DSM-5, nonverbal learning disability (NLD) is another category that has often been used to describe students with a specific profile of learning strengths and deficits. Rourke suggests NLD represents a cluster of neuropsychological, academic, and social emotional characteristics reflecting deficiencies in nonverbal processing and reasoning (Rourke and Tsatsanis 1996; Rourke et al. 2002). Generally, children with NLD exhibit assets in repetitive motor skills, learning through repetition and the auditory modality, verbal memory, receptive language,

phonemic awareness, word decoding, and spelling. Deficits, however, are notable in visual discrimination, visual-spatial organization, problem solving, pragmatics, mechanical math, reading comprehension, and social perception. Their challenges in social judgment, interaction, and emotion recognition compromise their abilities to maintain relationships with peers (Volden 2004).

Epidemiology

The National Institutes of Health and Centers for Disease Control and Prevention (2011) report about 15% of Americans, or one in seven, have some type of learning disability. The actual prevalence across academic areas ranges from 5 to 15% for school-age children (American Psychiatric Association 2013) with all cultures and language groups affected. More recent data for the 2013–2014 school year from the National Center for Education Statistics indicates more than 13% of school children (ages 3–21) are receiving special education services. Of all children currently receiving services, 35% have learning disabilities, and a majority of those children have reading as their primary academic challenge (Moats and Lyon 1993; U.S. Department of Education 2001;

Learning Disability, Table 2 Summary of learning disorders as described in the DSM-IV-TR and the DSM-5

Learning disorder	Description	Other terms used
Reading disorder	Difficulty with letter and word recognition	Dyslexia or developmental dyslexia – typically used to represent difficulties in word recognition and not the broader areas described for reading disorder which includes reading comprehension
	Poor phonemic awareness or phonological awareness (e.g., the ability to break up words into sounds, matching letters to sounds)	
	Difficulty understanding words and ideas or reading comprehension	
	Slower reading speed and poorer fluency	
	Weak vocabulary skills	
Mathematics disorders	Difficulties learning math concepts (such as quantity, place value, and time)	Dyscalculia – difficulty understanding math problems and time concepts, and using money
	Problems remembering math facts	
	Challenges organizing numbers and math problems	
Disorder of written expression	Difficulties with handwriting, spelling, organization of ideas, and composition	Dysgraphia – difficulty with handwriting; problems forming letters or writing within a defined space
Learning disorder not otherwise specified	May include problems in reading, math, and written expression that interfere with academic achievement even though test performance is not below age, IQ, or education level	

2015). Learning disabilities often have a familial risk. There appears to be equal gender representation with as many girls as boys having a learning disability, although the actual number of boys versus girls being served is different with more boys identified for and receiving services than girls (Bandian 1999; Coutinho and Oswald 2005).

Natural History, Prognostic Factors, and Outcomes

The learning disabilities field evolved from the influence of professionals and parents who were seeking an educational philosophy that would be responsive to the learning style and unique strengths and challenges of individual children (Smith 1998). The desired focus was that teachers would emphasize what a child could do and not just what they could not do. Through a variety of advocacy efforts (at both a federal level and a parent and professional organization level), a new disability category emerged in special education. Federal legislation giving all children the right to an equal education stimulated growth in

the field, and the enactment of P.L. 94–142 in 1975 assured special services for all children with disabilities. This was the first time children with learning disabilities were among those identified as disabled (Smith 1998). A reenactment of P.L. 94–142 in 1990 as the Individuals with Disabilities Education Act (IDEA; PL 101–476) advanced special services for students with disabilities, and the workforce saw growth in teachers prepared in learning disabilities as well as universities developing training programs in learning disabilities. A reauthorization of IDEA in 2004, now called the Individuals with Disabilities Education Improvement Act (IDEIA), offered an alternative approach to identifying children with learning disabilities. In the past, a learning disability was determined by an assessed discrepancy between achievement and intellectual ability in reading or reading comprehension, oral or written expression, mathematical calculation or reasoning, or listening comprehension. A change was made because of a lack of evidence that the IQ-achievement discrepancy formulas are consistently and reliably applied. Further, this approach has been problematic for students in poverty or

those with culturally and linguistically different backgrounds. The alternative approach to identifying whether or not a child has a learning disability is a response to intervention approach. This approach incorporates an evaluation of how a child responds to scientifically based intervention before making a determination if, in fact, the child has a learning disability.

Research has examined potential predictors of learning disability, including motivation (e.g., goal orientation, self-efficacy, self-concept, goal commitment, motivational force), metacognition (i.e., one's ability to monitor and control one's own learning), and psychopathology (e.g., depression and anxiety) (Sideridis et al. 2006). Results indicate that motivation is highly accurate in identifying students with or at risk for a learning disability with metacognition and psychopathology as strong predictors. Understanding these processes may facilitate our ability to more accurately screen and treat students with LD.

Although the causes of learning disabilities are unclear, it is noteworthy that learning disabilities tend to run in families. Pregnancy problems and difficulties at birth, anomalies in brain development, exposure to toxins, and accidents following birth are some examples of potential causal factors. A diagnosis of a learning disability has a significant impact on the family as it requires an understanding of the unique needs of the child and an ability to manage the learning, social, and behavioral challenges that often accompany the disorder. Learning disabilities impact an individual's ability to manage across their lifespan, and effective coping methods are critical.

Recent gains have been made in brain research examining the neuroplasticity of the brain and the role of brain-behavior findings in our understanding of disorders such as learning disabilities. The brain's ability to change and create new connections encourages applied research that examines the impact of evidence-based treatments on learning and increasing neuronal connections. In the right learning contexts, the brain might have an ability to reorganize old connections and create new connections that increases the ease of learning to read, write, or complete math calculations.

Clinical Expression and Pathophysiology

It is important to pay attention to normal developmental milestones for toddlers and preschoolers as early identification of developmental differences may be an early sign of a learning disability. Individuals with learning disabilities do not constitute a homogeneous group as the observed deficits occur in one or more domains of academic achievement including reading, math, and written expression (Fletcher et al. 2007). To understand the clinical expression and pathophysiology of a learning disability, it is important to recognize the potential influences on outcomes, which have variable expression. For example, there are neurobiological factors such as genetic profiles and brain structure and function differences that influence expression of the disorder. Environmental factors such as socioeconomic status, the amount and level of schooling, as well as the types of interventions received will affect outcomes. In addition, core cognitive processes (e.g., phonemic awareness) and behavioral/psychosocial factors (e.g., motivation, anxiety, attention) will have an impact on the characterization of the disorder for individual students. Thus, the traits that are described for learning disability or learning disorder exist on a continuum.

In the preschool years, some potential markers of a learning disability might be delayed speech and language, poor vocabulary growth, difficulty with phonological awareness (e.g., rhyming words, learning numbers, and letters), trouble following directions, difficulty with peers, and slow fine motor development. During early elementary school, some warning signs might be slower ability to connect sounds and letters, confusion with basic concepts, consistent reading and spelling errors, reversing letters or numbers, difficulty remembering math facts and telling time, and poor coordination. In the later grades, letter sequence reversals, difficulty with morphology (e.g., prefixes, suffixes, root words) and handwriting, avoidance of reading aloud and writing, poor recall, and difficulty making friends are likely behaviors.

Early intervention can reduce the number of children who qualify as learning disabled

(Sternberg and Grigorenko 1999, 2001). Although the provision of classroom accommodations supports the learning environment for students with learning disabilities, Sternberg suggests that schools often fail to recognize children's range of strengths and challenges, and instructional approaches may not be well suited to children's different learning styles. An integrated approach to identifying and supporting the needs of individuals with learning disability is recommended (Bradley et al. 2002; Fletcher et al. 2007). This approach considers the value of a response to instruction model for identifying children at risk, evaluating instructional quality and monitoring progress over time. It also identifies what to do when an inadequate response to instruction occurs. An integrated approach defines a path for more formal assessment in the learning domains as well as a comprehensive evaluation that probes potential language, social, and home factors that could produce underachievement (Bradley et al. 2002).

Evaluation and Differential Diagnosis

The process of diagnosing a learning disability is challenging as it requires not only accurate testing but also comprehensive data collection through a variety of sources. It involves testing, history taking, and observation by a trained specialist. Several professionals may be involved in the evaluation process, including a psychologist or neuropsychologist, an occupational therapist, a speech-language pathologist, and a special educator to name a few. During the diagnostic process, a number of professionals may be involved in coordinating efforts to obtain an accurate diagnosis which includes input from teachers, parents, and the student.

Currently, two approaches are used to identify learning disabilities: the IQ-achievement discrepancy approach and the response to intervention approach (RTI). In the IQ-discrepancy approach, intelligence and academic achievement testing, classroom performance, and social interaction are assessed. In addition, some students may receive speech-language and attention testing.

Assessment results determine if a student's academic performance is commensurate with cognitive ability. If cognitive ability or potential (as measured on an intelligence test) is well above a student's academic performance, then a diagnosis of a learning disability is made. Recently, however, this approach to diagnosis has been criticized because there is little evidence that the measured discrepancy is an indication of LD nor does it predict treatment effectiveness (Aaron 1995; Barnes et al. 2007; Harrison and Flanagan 2005). In the response to intervention (RTI) approach, the diagnostic process is more treatment oriented. All students are screened early on, and those demonstrating some difficulty receive research-based instruction prior to any identification of learning disability. Performance is monitored to determine if providing increasingly intense intervention facilitates the student's progress. Those who respond well to this intensive research-based instruction will not require further intervention or diagnosis, while those who do respond to regular classroom instruction (Tier 1 support) or intensive instruction (Tier 2 support) are referred to special education and are usually diagnosed with a learning disability. A benefit to this diagnostic approach is there is no waiting for the student to fail prior to receiving assistance. The 2004 reauthorization of the Individuals with Disabilities Education Act permitted states and school districts to use RTI as a method of identifying students with learning disabilities. Notably, this process does not consider individual neuropsychological factors that are often used to design instruction, it takes longer to implement the traditional approaches to assessment, it requires implementation of a strong intervention program, and it is driven by general education versus special education (Fletcher et al. 2007).

In the traditional approach to evaluation and diagnosis, several normed assessment tools are used to evaluate a student's academic performance and achievement. The primary academic domains that are assessed include reading, math and written expression, and achievement tests such as the *Woodcock-Johnson 4th edition* (WJ IV), the *Wechsler Individual Achievement Test 3rd edition*, the *Wide Range Achievement*

Test 3rd edition, and the *Stanford Achievement Test 10th edition*. Specialized reading assessment might also include *Gray's Diagnostic Reading Tests 2nd edition*, the *Stanford Diagnostic Reading Assessment 4th edition*, the *Comprehensive Test of Phonological Processing*, *Tests of Oral Reading and Comprehension Skills*, the *Test of Reading Comprehension 4th edition*, the *Test of Word Reading Efficiency 2nd edition*, and the *Test of Silent Contextual Reading Fluency 2nd edition*. Comprehensive assessment is certainly a requirement for intervention as well as helping to determine the contexts in which difficulties are experienced, including the coexistence of language and behavioral challenges.

It is important to recognize that other disorders are often confused with learning disorders and some may co-occur. Typically, those individuals with an intelligence level below 70 on a standardized intelligence test would be characterized as having an intellectual disability (formerly categorized as mental retardation) and would not also be diagnosed with a learning disability, although learning will be comprised for this population because of the identified cognitive impairment.

Attention deficit hyperactivity disorder (ADHD) and receptive and expressive language disorders often co-occur with learning disabilities, although these disorders are not included in the standard definition of learning disabilities. A child with an attention problem often struggles with

learning because of their inability to sufficiently focus on relevant stimuli and organize their responses. A child with a language disorder has difficulties at the core of learning disabilities, affecting listening comprehension and oral and written expression as well as pragmatic language function. All three disorders share executive function challenges and impact an individual's ability to communicate. These shared clinical manifestations complicate differential diagnosis.

Children with learning disabilities are also likely to have language and social challenges. For example, a nonverbal learning disability has a significant impact on an individual's ability to "read" facial and gestural cues during social interaction (Manoach et al. 1995; Rourke 1989). This can lead to odd and poor social behavior. Research is ongoing to determine the overlap or separation of NLD and ASD (Rourke 2000).

Treatment

National Institutes of Health (NIH) research suggests that 67% of students considered at risk for reading failure achieve average or above average reading performance following intervention in the early grades. As previously described, a new approach or conceptual model for intervention (i.e., response to intervention) is being applied to students with a learning disability so that a school

Learning Disability, Table 3 Examples and descriptions for interventions for children with learning disabilities

Examples of interventions	Description
Direct instruction (National Institute for Direct Instruction 2007)	Highly structured, individualized, and intensive instruction usually one-on-one occurring on a daily basis; lessons are preplanned to ensure small learning successes and identifying, and correcting mistakes immediately; progress monitoring is ongoing
Environmental arrangement or classroom adjustments	Modified assignments and testing procedures, preferential seating, quiet space to study and take tests, increased time for assignment or testing completion
Special equipment or learning materials	Access to word processors with spell checkers, voice output devices that use text to speech and speech to print programs, calculators, books on tape, etc.
Classroom supports	Notetakers, readers, proofers, scribes, instructional assistants, or paraeducators to support on task behavior and vigilant responsiveness
Special education	Specified hours or placement in a resource room, enrollment in an LD program, IEP, and related therapies
Speech-language pathologist	Addresses gaps in learning such as reading comprehension, pragmatics, written language

team can determine if a child responds to scientific, research-based instruction as early as possible. A primary focus of RTI is to identify the instructional challenges resulting from the learning disability and then implement high-quality instruction by well-trained educators to differentiate those children with a true disability and those with learning differences.

Treatment for individuals with LD involves a partnership with all team members including a case manager who implements the assessment process and coordinates the student's program; a special educator with credentials to support the specific educational needs of the student; a neurologist to address concerns about brain function and the implications on learning; a speech-language pathologist who provides support for speech, language, and social communication difficulties; and a psychologist who assesses psychological and intellectual development and guides treatment for behavior difficulties and mental and emotional health.

Several interventions are described in the literature, and several examples are summarized in Table 3.

Short Description or Definition

According to the DSM-IV-TR, a learning disorder can be diagnosed “...when the individual’s achievement on individually administered, standardized tests in reading, mathematics, or written expression is substantially below that expected for age, schooling, and level of intelligence. The learning problems significantly interfere with academic achievement or activities of daily living that require reading, mathematical, or writing skills.” The legal definition of a learning disorder has remained unchanged since 1977; according to the U.S. Department of Education, a specific learning disability is “a disorder in one or more of the basic psychological processes involved in using language, spoken or written, which...may manifest itself in the imperfect ability to listen, think, speak, read well, or do mathematical calculations.”

Categorization

In general, educators use the term learning disability while the medical community uses the diagnosis learning disorder. The U.S. Department of Education (1977) defines a learning disability as a severe, unexpected discrepancy between achievement and intellectual capacity in one or more of the following areas: (1) oral expression, (2) listening comprehension, (3) written expression, (4) basic reading skills, (5) reading comprehension, (6) math calculation, or (7) mathematical reasoning. The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR; American Psychiatric Association [APA] 2000) includes the following learning disorders: reading disorder, mathematics disorder, disorder of written expression, and learning disorder not otherwise specified. Diagnosed difficulties with oral expression and listening comprehension would be captured by communication disorder diagnoses: expressive language disorder, mixed receptive-expressive language disorder, phonological disorder, stuttering, or communication disorder not otherwise specified.

Epidemiology

Estimates of the prevalence of learning disorders range from 2% to 10% depending on definitions and how they are applied (APA 2000). According to Gregorenko (2007), prevalence rates for learning disabilities range from 5% to 12% of the total school-age population. When comparing the number of children who are receiving special services with the total school-age population, the prevalence rate is approximately 5–6% of the total school-age population. These estimates indicate that LDs are observed more frequently in boys than in girls and more frequently in underrepresented minority groups than in Asian Americans or whites. This method of estimating prevalence rates is somewhat flawed, however, as it relies upon each state's and school district's approach to identification and service provision for children with learning disorders and the proportion of children served in different states varies widely. According to Gregorenko (2007), estimates derived from research studies suggest that up to 10–12% of school-age children show specific deficits in selected academic domains. Provision of high-quality classroom instruction and supplemental small-group instruction may reduce this number to approximately 6% of children. It is assumed that these children would meet strict criteria for diagnosis of a learning disability.

Natural History, Prognostic Factors, and Outcomes

Historically, children have not been identified as having a specific learning disability until second grade or later. This is, in part, due to the fact that these children have intact cognitive functioning and have not fallen significantly behind academically in terms of age- or grade- based expectations until that time (e.g., have demonstrated an ability-achievement discrepancy). In 2004 with the reauthorization of the Individuals with Disabilities Act (IDEA), states and school districts were provided with the option of diagnosing learning disabilities using the traditional ability-achievement discrepancy model or an alternative

strategy known as response-to-intervention (RTI). RTI is an educational strategy in which all children receive continuous monitoring of academic progress. Children who exhibit difficulties are provided with evidence-based classroom remediation strategies. If these strategies prove to be ineffectual, the child is provided with more intensive, small-group instruction. If the academic difficulties are not remediated at this level of intervention, the child is referred for special education services and considered to have a specific learning disability. Because this strategy does not rely on waiting for a significant ability-achievement discrepancy to emerge before beginning to implement remediation strategies, intervention can begin at an earlier age in order to provide timely evidence-based remediation strategies and in an effort to prevent the development of other learning problems and comorbid disorders.

According to Mash and Wolfe (2005), about three quarters of children identified as having a reading disorder in elementary school still have major reading problems in high school and young adulthood. Children and adolescents with learning disorders are more likely than their peers to evidence both internalizing disorders, such as anxiety and mood disorders, and externalizing disorders, such as attentional or compliance difficulties. The American Psychiatric Association (APA 2000) states that the school dropout rate for adolescents with learning disorders is nearly 40% or approximately 1.5 times the national average. In addition, adults with learning disorders may have difficulty with employment and social adjustment. The APA estimates that 10–25% of individuals with learning disorders also have attention deficit hyperactivity disorder, oppositional defiant disorder, conduct disorder, major depression, or dysthymic disorder.

Many adults with learning disorders are able to find ways to accommodate their disabilities, build upon their strengths, and excel in their fields of endeavor. E.E. Werner, as part of a longitudinal study of all children born in 1955 on the island of Kauai, Hawaii, found that most children with learning disabilities she followed adapted successfully to adult life. Those who showed the

greatest resiliency had “(1) a basic temperament that elicited positive responses from others; (2) a well-developed sense of efficacy, preparedness, and self-esteem that guided their lives; (3) competent caregivers and supportive adults; and (4) opportunities for a second chance when they made mistakes or got into trouble with the law. Although some of the characteristics are present at birth (e.g., temperament), many of the other supportive factors can be increased through the efforts of family members, schools, and communities” (Mash and Wolfe 2005, p. 336).

Clinical Expression and Pathophysiology

Learning disabilities are thought to have a neurobiological basis, specifically atypicalities in brain maturation and functioning. According to Gregorenko (2007), the working assumption in the field is that genetic factors affect the development, maturation, and functional structure of the brain, which in turn influences cognitive processes associated with learning disorders. In addition, external risk factors, such as poverty and lack of educational opportunities, affect patterns of brain functioning and development. These external factors may worsen the prognosis for a biological predisposition for learning disabilities or serve as a trigger for their development.

Evaluation and Differential Diagnosis

Current methods of diagnosing learning disorders involve individual psychological assessment and/or a response-to-intervention model. In the psychological assessment model, an individual’s cognitive and academic strengths and weaknesses are assessed through a comprehensive evaluation. If a severe discrepancy between the individual’s cognitive and academic functioning is found that cannot be explained by normal variation in academic attainment, lack of opportunity, poor teaching, or cultural factors, then a learning disorder is suspected. Additionally, it is necessary to rule out impaired vision or hearing. It is possible to diagnose learning disorders along with mental

retardation, pervasive developmental disorder, or communication disorders when “academic impairment is significantly below expected levels given the individual’s intellectual functioning and schooling” (APA 2000). The educationally based response-to-intervention model involves early, continuous monitoring of all children’s academic achievement. If children fall behind their peers, they are provided with high-quality research-based, small-group instruction and their progress is continually monitored. If, over time, this level of intervention is not sufficient to bring the child’s skills up to grade level, then the child is diagnosed as having a learning disability and provided with special education services.

Treatment

Interventions for learning disorders are primarily educational, rather than medical, in nature. A direct behavioral instruction approach is often used; tasks are broken down into manageable steps with ample examples, practice, and feedback. For example, Mash and Wolfe (2005) state that children with reading disorders must be taught phonemic awareness and phonemic decoding skills, fluency in word recognition, construction of meaning, vocabulary, spelling, and writing. When direct and explicit instruction in these components is provided, data show dramatic reductions in reading failure. According to Shaywitz (2003), the specific program chosen for remediation is less important than the fact that a scientifically proven program is provided by highly qualified teacher with sufficient intensity and for a sufficient length of time. Mash and Wolfe (2005) also indicate that cognitive behavioral interventions have also been found to be useful for children with learning disorders, particularly for tasks that involve monitoring one’s own thought processes. “Essentially, children are taught to ask themselves several questions as they progress, to make themselves more aware of the material. . . Why am I reading this? What’s the main idea the authors are trying to get across? Where can I find the answer to this question? How does this follow from what I learned a minute

ago?” (Mash and Wolfe 2005, p. 342). Finally, computer-assisted learning programs have been found to be helpful in providing opportunities for practice, feedback, and drills.

Learning Experiences, an Alternative Program for Preschoolers and Their Parents (LEAP)

Evelynne Green
The University of Vermont, Burlington, VT, USA

Definition

Learning experiences, an alternative program (LEAP), is a model of early intervention that serves children with autism spectrum disorders (ASD) and typically developing children in an inclusive preschool setting. The program was developed to support the social and communicative skills of children with ASD

through a peer-mediated approach (Strain and Bovey 2008). Typical children are taught to use a series of strategies to engage classmates with ASD in social interaction. Training involves explicit teaching, role play, adult cueing and scaffolding, and positive reinforcement. Opportunities for social engagement between typical peers and children with ASD occur within the context of a preschool curriculum designed to facilitate the learning and development of both typical children and those with ASD.

Historical Background

The LEAP program was developed in 1981 by Dr. Phillip Strain. It began as a federally funded demonstration program in Pittsburgh, Pennsylvania, and was one of the first inclusive educational programs, serving children with ASD and their typical peers (Kohler et al. 1996). In 1984, LEAP began to set up replication sites, which provided general training to school districts across the United States and several foreign countries. In 1988, Douglas County, Colorado, became the primary demonstration site for the LEAP program, and as of 2008 over 80 LEAP preschool programs had been established (Strain and Bovey 2008).

Rationale or Underlying Theory

The LEAP program is based on current research suggesting that children with deficits in social communication benefit from peer-mediated intervention in an inclusive setting. To develop the social-communication skills that allow for the development of appropriate peer relationships, children with ASD must be provided with adequate opportunities to interact with typically developing peers (Strain et al. 1998). Inclusive classroom settings can be advantageous because opportunities for social interaction occur on a daily basis. However, Strain et al. (2008) point out that simply placing a child with ASD in an inclusive setting with typical peers does not in and of itself facilitate social interaction. Typically developing peers require instruction regarding

how to interact with their classmates with ASD in order to maximize appropriate development of social communication. Strain and Bovey (2008) cite several studies indicating that typically developing children as young as 36 months can be trained to use strategies that support the social communication of children with ASD, resulting in higher rates of communicative interactions, and that many children with ASD who participate in peer-mediated intervention eventually develop social-communication skills that are considered developmentally typical.

Goals and Objectives

The primary goal of the LEAP program is to support the development of appropriate social-communication skills through peer-mediated intervention. One of the core deficits of children with ASD described by *The Diagnostic and Statistical Manual of Mental Disorders-Fourth Edition* (DSM-IV; American Psychiatric Association 2000) is a qualitative impairment in social interaction, which is frequently characterized by a failure to develop appropriate relationships with peers and a general lack of social reciprocity. The LEAP program incorporates explicit instruction in social-communication strategies into its general curriculum, and typical peers are trained to facilitate the social communication of children with ASD.

Treatment Participants

There are currently no set guidelines to determine eligibility to participate in the LEAP program. Because there is a primary focus on developing social-communication skills and fostering successful peer relationships, children who exhibit deficits in these areas would be candidates. Strain and Bovey (2008) indicate that all children participating in efficacy studies have met the diagnostic criteria for “early childhood autism” on the DSM-III and DSM-III-R. However, it is likely that children with other diagnoses characterized by deficits in social communication would benefit from

this intervention. Specific diagnoses might include childhood disintegrative disorder (CDD), Asperger’s disorder, and pervasive developmental disorder not otherwise specified (PDD-NOS). Participants should be approximately 3–5 years of age, as the intervention is provided within a preschool setting.

Children participating in the LEAP program may have a range of verbal language ability. The program supports the development of verbal language through a variety of naturalistic approaches including incidental teaching and time delay (Strain and Bovey 2008). Additionally, the *picture exchange communication system* (PECS), along with other low-tech and high-tech augmentative and alternative communication systems, has been successfully incorporated into LEAP classrooms, providing communication modalities for children who have little to no verbal language (Strain and Bovey).

Treatment Procedures

LEAP classrooms typically operate 5 days a week for 3 h a day. Each classroom includes 3–4 children with ASD, 8–10 typically developing peers, and at least three adults, who may include an early education teacher, early childhood special education teacher, speech-language pathologist, occupational therapist, and classroom assistant (Strain and Bovey 2008). The program features full-time inclusion, so children with ASD participate in all the same classroom activities alongside their typically developing peers. Every classroom utilizes a general preschool curriculum, along with a social skills curriculum. Although there is variation among sites, most LEAP classrooms utilize the *Creative Curriculum for Preschool* (Dodge et al. 2002) and/or the *Storybook Journey: Pathways to Literacy Through Story and Play* (McCord 1995) to guide the general curriculum (Strain and Bovey 2008).

The LEAP social skills curriculum consists of five social skills: getting a friend’s attention, sharing, requesting sharing, play organizing (“Let’s _____” statements), and giving compliments (Strain and Bovey 2008). These skills were

specifically chosen based on evidence that they facilitate longer interactions between children and support the development of friendships (Kohler et al. 1992). Skills are taught one at a time until children demonstrate understanding of the steps involved and are able to utilize the skill independently during play. Each skill is taught in six basic steps (Strain and Bovey 2008):

- *Step 1 Describe:* The skill is introduced and described, and any steps that are involved in the skill are explained. Visual images depicting the skill are utilized to facilitate understanding. For example, when describing “getting a friend’s attention,” the interventionist might say, “Today we are going to learn how to get our friends to play with us, because it is important that friends learn how to play together. One way to get your friend to play with you is by getting their attention.” The interventionist then details the steps of the skill: “To get your friend’s attention you can look at your friend, tap them on the shoulder, and say their name. If you don’t get their attention right away keep trying.”
- *Step 2 Demonstrate the Skill:* Two adults demonstrate the skill being taught. For example, the interventionist might say, “Let’s practice getting a friend’s attention. I’m going to get Kate’s attention. Tell me if I do it right.” The interventionist then role plays the scenario with the other adult and reiterates what happened.
- *Step 3 Demonstrate the Wrong Way:* Two adults demonstrate the skill again, but do it the wrong way. Following the demonstration, the interventionist asks the children to point out what was wrong with the interaction. For example, the interventionist might tap the other adult on the shoulder, but forget to say her name.
- *Step 4 Child Practice with Adult:* The interventionist reviews the skill and then calls on a child to demonstrate it for the class. The interventionist might say, “Now I want you to show the class how to get your friend’s attention. Let’s pretend I’m your friend and you want to get my attention. Remember to look at me, say my name, and tap me on the shoulder if I’m not looking.”
- *Step 5 Practice with Target Child:* The interventionist reviews the skill again and then instructs the typical peer to practice the skill with the child with ASD.
- *Step 6 Awards and Prizes to Students:* The interventionist awards prizes to reinforce children’s use of the skills being taught. Specific praise is also provided that explains why the child is receiving a prize, such as “Good work, you got your friend’s attention” or “Nice job looking at your friend.”

The LEAP program also incorporates several naturalistic teaching strategies in order to facilitate learning and development of skills throughout the day in a variety of situations. These strategies include incidental teaching, mand-model procedures, time delay, and pivotal-response training (PRT), along with general prompting and modeling by adults (Strain and Bovey 2008). Incidental teaching involves arranging the environment in a way that promotes communicative behavior. For example, desired objects might be placed out of reach so that the child must request them. In the mand-model procedure, the interventionist first prompts the child to communicate by asking a question (the mand) (e.g., “what do you want?”), followed by a model of the target behavior (e.g., “say, I want the bubbles”). When using time delay, the interventionist waits approximately 5–10 s before assisting a child who is having difficulty obtaining or using a desired item with the goal that the child will initiate a request for help. PRT is a technique based on the principles of applied behavioral analysis (ABA) that involves rewarding and shaping attempts at a target behavior. Rewards are in the form of natural reinforcers so that if a child asks for a hat, she receives the hat as a reward as opposed to an unrelated reward, such as a piece of candy.

Family involvement is an integral aspect of the LEAP program. Services available to families participating in the program include training focusing on strategies for behavior management and teaching new skills to children, monthly parent support groups, referral to community

agencies offering relevant services such as respite care, and transition planning and follow-up services (Strain and Bovey 2008). Families are taught to implement certain intervention strategies used in the classroom at home to facilitate the generalization of skills. Families also participate in some aspect of the preschool program ranging from assisting in the creation of instructional materials and preparing activity centers to providing direct intervention (Strain et al. 1996).

Efficacy Information

To date, only one study has assessed the efficacy of the LEAP program as a whole. Strain and Hoyson (2000) conducted a longitudinal study evaluating intervention outcomes for six children enrolled in the LEAP program. Participants were assessed prior to beginning the program and upon completion of the program (2–3 years after beginning the program). Follow-up measures were taken approximately 4 years after completion of the program when the children were 10 years of age. At baseline, all participants fell within the moderate to severe range of autism on the *Childhood Autism Rating Scale* (CARS; Schopler et al. 1988), with a mean score of 35. Upon completion of the program, participants no longer met criteria for autism on the CARS. Participants also exhibited significant increases in the appropriateness of their behavior during interactions with caregivers. At baseline, the mean time engaged in appropriate behavior with caregivers was 51%. Upon completion of the program, participants demonstrated appropriate behavior with caregivers 98% of the time, and parent ratings of behavior rose from “very unacceptable” to “very acceptable.” Additionally, participants’ mean percent of intervals engaged in positive social interaction rose from 3% at baseline to 23% upon program completion. This is comparable to the performance of typical peers whose mean percent of intervals engaged in positive social interaction was 28% and 25% at baseline and program completion, respectively. All program outcomes were maintained at follow-up, 4 years following completion of the program.

The participants described by Strain and Hoyson (2000) were the first participants to complete the research protocol for the LEAP program. An additional 45 children have since been enrolled in the research protocol with the intent of replicating results of the current study in the future (Strain and Hoyson 2000). Although this single study provides limited evidence for the efficacy of the LEAP program as a whole, the effectiveness of the peer-mediated intervention strategies, such as those utilized in the LEAP program, has been widely studied. Current evidence suggests that peer-mediated interventions are effective in increasing both the frequency and duration of social interactions between children with ASD and their typically developing peers (e.g., Laushey and Heflin 2000; Odom and Strain 1986; Ragland et al. 1978; Strain et al. 1979; Roeyers 1996). Based on the positive outcomes demonstrated by Strain and Hoyson (2000) and the well-documented effects of peer-mediated intervention strategies in general, the LEAP program is considered to be efficacious intervention for promoting the development of social-communication skills and appropriate peer relationships in children with ASD.

Outcome Measurement

The LEAP program utilizes a tracking system that measures children’s progress toward individualized objectives in terms of level of independence (Strain and Bovey 2008). Children’s level of independence for each objective is rated daily on a scale from 0 to 4, with a score of 0 indicating that the child refuses to perform the skill and a score of 4 indicating that the child performs the skill independently without adult assistance. Interventionists set criteria for each level that the child must meet before moving to the next level of independence. For example, the child might have to exhibit performance at a level 2 (adult provides partial physical assistance) for 6 out of 7 days before moving to a level 3 (adult points/gestures/models or verbally directs the child). As children move up the scale, the interventionist adjusts their behavior to match the ability of the child.

Qualifications of Treatment Providers

Although Strain and Bovey (2008) note that LEAP staff configurations vary, service providers may include early education and special education professionals, speech and language pathologists, occupational therapists, and trained classroom assistants. Additionally, each classroom typically has at least one teacher with a master's level education (Strain et al. 1996). All staff are provided training through the LEAP program.

Learning Language Through Overhearing in Children with ASD

Rhiannon J. Luyster¹ and Sudha Arunachalam²

¹Department of Communication Sciences and Disorders, Emerson College, Boston, MA, USA

²New York University, New York, NY, USA

Language development in the early years of life is of utmost importance for children with autism spectrum disorder (ASD), whose early linguistic skills are strong predictors of a variety of social, adaptive, and academic outcomes. Documenting which mechanisms are and are not contributors to mastery of fundamental language skills is therefore of central clinical (and theoretical) importance (e.g., Arunachalam and Luyster 2016).

Typically developing children have an arsenal of strategies for learning new words in infancy and beyond. Although the prototypical word-learning context for many cultures as well as most research studies is that of “child-directed speech” – settings in which a caregiver explicitly directs a novel word to the child, usually in a 1:1 interaction – children can acquire new words from a broader range of experiences. For instance, toddlers are proficient at learning new words even when they are eavesdropping on a third-party conversation; this skill has been documented in laboratory-based tests (e.g., Akhtar et al. 2001), and cross-cultural research has confirmed the ability of children to learn across a wide range of linguistic contexts (e.g., Ochs and Schieffelin 1984).

Exploring the question of whether children with ASD are able to learn new words via overhearing has the potential to enrich our understanding of what aspects of language development in ASD are “intact” (e.g., Arunachalam and Luyster 2016). Given associations between language input and language mastery for children with ASD, this inquiry also has the potential to support caregivers, clinicians, and therapists in enriching the early language environments of children with ASD.

The first study exploring the ability of children with ASD to learn language by overhearing was a “proof of concept” study (Luyster and Arunachalam 2018) asking whether, in a laboratory setting, children with ASD were able to learn new nouns through overhearing others use them in conversation. The final sample included 13 children with ASD (ages 4 and 5 years old), for whom diagnosis was confirmed using the Autism Diagnostic Observation Schedule – 2nd edition (ADOS-2). Based on scores from the MacArthur Bates Communicative Development Inventory forms II and III (MBCDI) and Language Use Inventory (LUI), children’s communication skills were roughly at the 28-month developmental level.

Using a within-subject design and a paradigm based on previous research (Akhtar et al. 2001), each child was taught new object labels in both directly Addressed (i.e., the experimenter spoke directly to the child) and Overheard (i.e., the experimenter spoke only to a confederate; the child was only an onlooker) training conditions. Each experimental condition (i.e., Addressed, Overheard) used a different novel word (*modi*, *toma*) to introduce one of three novel objects. When introducing the target object, the phrases included a novel label for the object (e.g., “I’m going to show you the toma. Let’s see the toma... I like this toma!”). When introducing nontarget items, the phrases were similar but did not include an explicit label (“I’m going to show you what’s in here. Let’s see what’s in here. I like this one!”). After each training round was completed, the child was asked to identify the target object and place it in a small, decorated bucket.

Overall, children succeeded in the task; they chose the correct novel object 62% of the time in the Addressed condition and 69% of the time in the Overheard condition. Chance performance is 33% given that three novel objects were presented. Binomial tests on the data from each condition were used to determine whether performance was above chance. In the Addressed condition, a binomial test indicated that the observed success rate of 67% was significantly higher than the chance level of 33%, one-tailed

$p < 0.04$. In the Overheard condition, too, the success rate (69%) was significantly higher than chance, one-tailed $p < 0.01$.

These results are consistent with prior research with typically developing children (e.g., Akhtar et al. 2001) and provide new information about the ability of children with ASD to learn through overhearing. In this study, children with ASD succeeded in both Addressed and Overheard contexts, indicating that at least some children on the spectrum can learn nouns from overheard speech. This may inform strategies that clinicians can use to promote language development for some children with ASD, especially those who are overwhelmed by social interactions. It may also be useful for learning personal pronouns, which – for typically developing children – seem to be facilitated by access to overheard speech (e.g., Oshima-Takane 1988).

Learning Styles

Hilary Boorstein¹, Harriet Levin² and Deborah Fein³

¹Children's Mercy Hospital, Kansas, MO, USA

²University of Connecticut, Storrs, CT, USA

³Department of Psychological Sciences, University of Connecticut, Storrs, CT, USA

Definition

Learning styles refer to how someone learns best, with the implication that the primary mode of instruction (visual, auditory, kinesthetic, etc.) should be matched to the individual's preference and ability. This idea has gained great currency in general education, but a recent review of empirical evidence (Pashler et al. 2009) concludes that the theory lacks empirical support and should not be the basis of general educational strategy. In the field of special education, however, despite lack of rigorous empirical studies, educational strategy is influenced by the very significant language impairments of children with ASD, which makes them better able to learn and perform tasks with prominent visual or visuospatial components, both to get and hold their attention, and to facilitate comprehension and retention. Many individuals with ASD appear to learn best when provided with visual cues and instruction. This appears true for individuals with ASD with and without intellectual disabilities. This preference for visual learning is the basis for many interventions, including the picture exchange communication system (PECS), visual schedules, and many of the TEACCH strategies. One other dichotomy may be drawn between explicit and implicit learning: The former refers to conscious, intentional learning of facts, rules, and events, which can be learned in a single trial, while the latter refers to automatic, rote, learning of habits and procedures that are mainly learned by repetition. For individuals with ASD and significant intellectual disability, the latter may be a more efficient style of learning. This would involve emphasizing learning goals, such as activities of daily living and

simple communication such as pointing to a desired object, that can be learned through repetition and may need more teaching than usual to be generalized.

Least Restrictive Environment (LRE)

Debra Dunn

The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Synonyms

Appropriate educational placement; Inclusion

Definition

Least Restricted Environment (LRE) is a policy mandated by federal law, which requires that students be educated to the greatest extent appropriate with peers who are not disabled, in the schools they would attend if they were not disabled. The requirement extends to both academic and extra-curricular programming. LRE is imposed on all states receiving federal education funding and applies to students aged 3–21.

There is no one definition of LRE. Rather, LRE placement must be individualized for each student

and is not predetermined based on a student's disability or other factors. Instead, the appropriate educational placement (the LRE) must be determined by the IEP (individualized education plan) team.

The IDEIA (Individuals with Disabilities Educational Improvement Act) and its predecessor, the IDEA (Individuals with Disabilities Education Act), express a strong preference for educating students with disabilities in regular classrooms (also known as inclusion), but they recognize that inclusion may not be appropriate for all students. School districts must offer a continuum of services to meet the needs of students with disabilities. When making placement decisions, IEP teams must first consider a regular education classroom placement and must move down the continuum until finding the appropriate place and manner for educational services to be delivered. Accommodations (referred to as supplementary aids and services by the IDEIA) that would enable a student to be in a more inclusive setting must be considered. Examples of accommodations that may be helpful for students with autism spectrum disorders include curriculum modifications, effective behavioral supports, teacher training, and assistive technology.

The principles of LRE stem from the seminal case of *Brown v. Board of Education*, whose opinion established the importance of education for all children. Since *Brown*, federal courts considering cases brought under the IDEA have repeatedly recognized the academic, social, and behavioral benefits of educating children with disabilities with typical peers.

Lebanon and Autism

Leyla Akoury Dirani and Hala Raad
Division of Child and Adolescent Psychiatry,
Department of Psychiatry, American University
of Beirut Medical Center, Beirut, Lebanon

Country Background

Lebanon is a Middle Eastern country of 10,452km², a population of 4 million Lebanese citizens, more than one million registered Syrian refugees, and 500,000 registered Palestinian refugees. Since its independence in 1943, Lebanon has been a land of war-related turmoil, internal conflicts, and social and economic struggles. All the economy is based on the efforts of the private sector.

Historical Background

The worldwide prevalence of children and people with autism spectrum disorder has been on the rise in the past few decades (El Sabbagh et al. 2012). Research studies conducted in Arab countries indicated a lower prevalence rate than the worldwide estimated prevalence of 62/10000. For example, the United Arab Emirates estimated the prevalence of 29/10,000 (Eapen et al. 2007), Bahrain found a prevalence of 4.3/10,000 (Al-Ansari and Ahmed 2013), the Sultanate of Oman found 1.4/10,000 (Al-Farsi et al. 2011). It was argued

that the lack of standardized and culturally sound tools and procedures, as well as the lack of qualified professionals in diagnosing Autism Spectrum Disorder (ASD), explains this finding (Obeid et al. 2015). Although there are no epidemiological studies on ASD in Lebanon, there is an increase in referrals for ASD to clinicians from as early as the age of 18 months.

The history of the disability field in Lebanon goes back to the Ottoman Empire when the first law in 1876 dealing with “*mentally ill*” people was proclaimed and implemented (Raad 2000). Persons with disabilities were subject to negative terminologies and placed in asylums (Megarbane 1996). In 1973, the first disability categorizations were stated in the law 11/73 which defined persons with “handicap” and differentiated between the *mentally* and the *physically* handicapped people (Raad 2000). In 2000, the Lebanese parliament approved the most recent disability law 220/2000 which for the first time introduced the notion of rights as an underlying principle to disabilities. This law divided people with disabilities in four categories: intellectual disability, visual disability, hearing disability, and physical disability. Autism Spectrum Disorder (ASD) is therefore not considered as an independent category in the Lebanese legislation. Persons with autism are counted under Intellectual Disability (ID) in the national statistics, which constitutes a major bias. In 2004, the Central Administration of Statistics (CAS)’s report indicated that 2% of the Lebanese residents have a disability and 18.4% of them have an intellectual disability. These figures are taken from the Ministry of Social Affairs registry (MOSA) that is not exhaustive of all individuals with disabilities.

The first educational program dedicated for children with autism was founded in 1989 by a nongovernmental organization (NGO). It started with 12 children aged between 8 and 12 years old. The professional team was composed of four special educators, a child psychologist, and a social worker. The program’s aim was to provide each child with a stimulating learning environment, and to address his/her problem behavior. Every 2 to 3 children were grouped with one special education teacher. Parents were provided with

social and psychological support and guidance. No specific school of thoughts was chosen. Later, the program tried to implement the principles and techniques of the Treatment and Education of Autistic and Related Communication-Handicapped Children (TEACCH) (Mesibov et al. 2005). A French approach the “*Thérapie d’échange et de développement* (TED)” (Lelord et al. 1991; Barthelemy et al. 1995; Bataille et al. 2010) is introduced in the early 2000. TED is very similar to TEACCH in the one-to-one setting.

In 1996, the first privately owned early intervention center was opened for children below the age of 4, presenting with autism. With a full capacity of 9 children, the center operated for 4 years and closed short of financial resources. The team was composed of special education teachers, a speech therapist, a psychomotor therapist, a child psychologist. A parents’ support group was established; it became later the first parents’ advocacy group for children with ASD.

As of the year 2000, more programs for children with autism became available, with more specialized interventions and skilled professionals. Lebanon counts now around 13 NGOs offering specialized programs covering early childhood, childhood, and early adulthood. These NGOs operate in a holistic approach more empirically based than designed within an evidence-based therapeutic framework. Children enrolled in their programs have moderate to severe ASD, associated with Intellectual Disabilities.

More recently, a major effort in the early diagnosis of autism is made with the increased number of specialized physicians and allied health professionals established in Lebanon. A handful number of centers are specialized in early assessment and early intervention. More specifically, two centers in a tertiary care facility in Beirut opened in 2011 and in 2014. The first one provides pediatric neurology and individual rehabilitation assessments and follow-up services in the areas of speech therapy, physiotherapy, applied behavioral analysis, psychomotor therapy, and occupational therapy. The second center provides child psychiatry, clinical psychology, and special education assessments and services. These two

centers have a strong team-based approach. They base their work on international standards of care and embed their assessments and interventions on evidence-based tools and techniques.

The advances in service provision have contributed to greater awareness among people in society, leading to changes in perception, mentalities, and quality of care and services (Obeid et al. 2015). Activists’ groups, mainly parents of children with ASD, established NGOs and lobby for their children’s rights through advocacy work at the policy level and the creation of educational and vocational services. In addition, the movement of inclusive education initiated in the 1990s becomes stronger lately. This helps children with mild ASD to be maintained in regular schools.

Legal Issues, Mandates for Services

Lebanese citizens with disabilities are under the jurisdiction of the MOSA, specifically under the broad umbrella of welfare services. As stated above, the only law (220/2000) pertaining to secure their rights in all domains, education, health, work, etc., was issued in 2000. The text is comprehensive, comparable with other jurisdictions in western countries. However, it has not been fully enforced. A person needs to register at the MOSA and receive a disability card. Card holders can then benefit from some tax deductions, access to NGOs’ educational and rehabilitation programs, if the NGO has signed an agreement with MOSA. The NGOs offer services for low fees but no quality control is performed. Various persons with disabilities choose not to get the disability card which they consider to be discriminative.

Lebanon hosts since 1948 Palestinian refugees who receive support from the United Nation Relief and Works Agency for Palestine Refugees in the Near East (UNRWA). UNRWA mandate is to support medical, educational, and rehabilitation services for 450,000 individuals in the 12 Palestinian camps. UNRWA has not developed a specific program to address the needs of individuals with ASD.

As per the United Nations High Commissioner for Refugees (UNHCR), up until December 2016, more than million Syrian refugees fled to Lebanon and 45% of them are children. The UNHCR, international and national NGOs ensure the basic needs only. Nothing is available for individuals with ASD.

The absence of legal framework specific to ASD, the limited access to quality care through governmental and United Nations bodies, pushed the civil society to fill the vacuum. NGOs and charity initiatives assist parents with low incomes in providing their children with ASD with basic services.

Diagnostic, educational, and rehabilitation services are also provided by the private sector, most professionals working in Beirut and its surrounding. The social security and the insurance companies cover the medical treatment only. Psychological and rehabilitation services are not covered. This creates a huge burden on individuals and their families, delays diagnoses, and jeopardizes the access to, and the, continuity of care.

Overview of Current Treatments and Centers

Two centers located in a private tertiary care facility offer diagnostic assessment based on the DSM 5, and specialized follow up. Clinical assessment was supported with a variety of tools such as the Autism Diagnostic Observation Schedule (ADOS-2), the Arabic version of the Childhood Autism Rating Scale (CARS-2) (Akoury-Dirani et al. 2013a, b), and neurological and genetic testing. Other professionals in the private sector assess autism using clinical observation, and parents' informal interviews.

To date, children with disabilities, including those with ASD, may benefit from different academic modalities depending on the severity of their conditions, the availability of services in geographical areas and parents' choice, financial means, awareness, and perception of disability. Another impactful criterion is whether the child has been subject to early intervention services

which would enable him/her to enroll smoother into a school setting.

One option is the private disability centers or institutions. Currently around 13 NGOs offer a day program for children, adolescents, and young adults with moderate to severe autism, with or without dual diagnoses. Most of these grassroots organizations are in the capital city Beirut and its suburbs with some located in Mount Lebanon (the closer Governorate to the capital) and few scattered in further Governorates such as the North, East, and the South. They are either founded by parents of children with ASD or by religious and other civil society entities. Beneficiaries are grouped by severity levels. The educational program covers the contents of the first elementary school cycle. Individual sessions of speech and occupational therapy as well as special education may be offered, in addition to social support for parents. When the NGO is sub-contracted by MOSA, the tuition fees are minimum.

The second option is the inclusion of children in regular private schools. The child is either in the regular classroom accompanied by a shadow teacher or enrolled in a self-contained class in parallel with the regular ones. The child may be also partially attending the regular class and benefiting from individualized pull out sessions in the resource room. In addition to the modified academic curriculum or the Individual Educational Program, the schools provide rehabilitation services such as speech therapy, psychomotor therapy, counseling, and special education.

Inclusive education remains however an expensive option. Tuition fees for children with ASD are double or triple the regular tuition fees for the same grade level; it varies depending on the amount and intensity of academic accommodations and rehabilitation of services needed by the child.

Lately, two privately led inclusive education projects are implemented in 240 public schools as a collaboration between NGOs and the Ministry of Education and High Education (MEHE). The third inclusive education project is a public initiative led by MEHE and implemented in 20 public schools across Lebanon. These pilot

projects target students with learning disorders. If the model succeeds, it is said that it would be expanded to other categories such as students with ASD.

Over the past decade, Lebanon has been witnessing a higher ratio of young children (1–3 years old) being referred to specialized professionals (psychiatrists, psychologists, pediatric neurologists) for diagnosis of ASD. An effort is made on addressing the very early stages of child development. Two early intervention programs (zero to three) exist in Beirut offering diagnoses, assessment, and treatments.

These children are then referred to nurseries where they can be provided with adequate support. Some nurseries have special education interventions and/or more frequently other rehabilitation services such as psychomotor and speech therapists.

Finally, the Applied Behavior Analysis (ABA) has been shyly introduced in Lebanon about 20 years ago. It received initially a lot of resistance from the community of professionals and parents. More recently, less than 10 professionals have been certified in ABA and they operate in private practice. They may either deliver individual session in their office or do home-based interventions.

Overview of Research Directions

Eleven articles were published between 2001 and 2017 in indexed peer-reviewed journals. Scholars worked on prevalence studies, validation of scales, suicidality and autism, early intervention, and genetics.

One prevalence study done in 2016 by Chaaya et al. (2016), on toddlers between 16 and 48 months attending nurseries in Beirut and Mont Lebanon, estimated the prevalence of ASD to be 153/10,000. This prevalence is higher than those published in Arab studies but close to the 147/10,000 reported by the CDC in 2014 (CDC 2014). However, the representativeness of the sample and the usage of the M-CHAT, a screening tool to estimate prevalence, may limit the generalizability of the results. Another study tried to describe the most prevalent associated factors

with ASD (Hamade et al. 2013). The small sample size could not derive conclusive findings.

Three papers were published on the translation to Arabic and the validation of scales supporting the assessment of ASD. One was on the translation and the validation of the Revised Autistic Behavior Summarized Evaluation Scale (BSE-R) (Hreich et al. 2016). The two others were on the translation to Arabic and the validation of the Childhood Autism Rating Scale 2nd edition (Akoury-Dirani et al. 2013a, b).

Two nonconclusive genetic studies were conducted (Kourtian et al. 2017; Soueid et al. 2016).

Two studies described interventions. One targeted the description of speech and language therapy for children with ASD (Kouba-Hreich et al. 2001). The second was a case study on three children aged between 5 and 6 years, who were trained through ABA to take leisure activities independently (Daou 2014).

One study targeted knowledge and social perception of ASD (Obeid et al. 2015). It compared between college students in the USA and college students in Beirut-Lebanon. At baseline, students from Lebanon reported less overall knowledge and higher stigma towards ASD – they were more knowledgeable than students in the USA about disparities in access to care.

Finally, one literature review on suicidality in ASD was conducted and published in a peer-reviewed journal (Richa et al. 2014).

In addition, a voluminous grey literature produced by graduate students from different majors like psychology, special education, speech and language pathology, occupational therapy merits to be explored if we want to build a research strategy or program based on some previous data. In conclusion, the topic is of interest among junior professionals and some scholars. Short of specific research programs, the research initiatives are scattered, established on individual efforts, and supported with limited funding.

Overview of Training

Universities include the theme of autism in their teaching in degrees that are related to the field:

medicine, psychology, education, etc. One academic center includes the TED approach in the training of speech therapists.

In the early 2000, a European NGO funded a large project pertaining to empowering local NGOs offering educational and rehabilitation programs specific to children with autism. This 3-year project deployed a series of on-site training sessions. Special educators, speech therapists, and psychomotor therapists benefited from theoretical information, and hands-on skills. This training contributed to spread the same “professional culture” when it comes to working with persons with autism and their families. Occasionally, an NGO or a University would invite an expert to give a talk or a workshop on autism.

Social Policy and Current Controversies

Addressing the needs of the persons with autism remains an important challenge in Lebanon, as it is for all other disabilities. The national classification of disabilities includes ASD under ID. This shows a major misconception about this disorder. Within the same line, the diagnosis of very young children and of children with mild autism when possessing verbal abilities is rarely posed (Akoury-Dirani et al. 2013b). Diagnostic confusion between mild ASD, Attention Deficit and Hyperactivity Disorder (ADHD), and Disruptive Behavior is clinically observed.

The most important drawback is the absence of national policies guaranteeing rights, guiding the provision of services, controlling for quality, and encouraging research. All accomplishments are based on private initiatives and out of pocket money or private fundraising efforts. The limited financial resources collected for this cause added to the impoverishment of the population, draining the support towards covering the immediate and basic needs of persons with ASD.

Another source of concern is the concentration of the few experts and professionals in Beirut and its surrounding. Therefore, even when individuals live far from the capital and have the financial resources, they cannot access proper care.

The absence of formal social skills training for children and adolescents with ASD contributes to maintaining them in a constricted environment. Some adults, and aging people with moderate to severe autism, are maintained in institutions where they work in sheltered vocational activities while most of them are homebound.

Within this challenging context, parents of children with autism started their rights-based advocacy movement since the 1990s. Two associations exist. Their advocacy movement changed the knowledge and perception about autism. Marathons, fundraising events, awareness campaigns, and media appearances are done by such organizations and other supporting members from the society. This movement also led to the increase of early diagnoses and professional interventions as well as the financial support to create educational settings for children with ASD and fund research projects.

Legal Competency

Michael Levine and Alyse Greer
Quinnipiac University School of Law, Hamden,
CT, USA

Definition

Legal Competency

Legal Proceedings

The 1960 Supreme Court decision in *Dusky v. United States* articulated the following standard of legal competence: “[T]he test must be whether he has sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding and whether he has a rational as well as factual understanding of the proceedings” This legal standard has been cited in numerous cases since *Dusky* and thus appears as a durable definition. That said, the exact standard does vary by jurisdiction. All jurisdictions agree that the definition may not be a rigid one. Legally, it defies a precise “one size fits all” definition.

Medical Decisions

Healthcare professionals assess the patient's capacity to give informed consent or make

informed decisions based on the patient's ability to understand the treatment, the alternatives, and the risks associated with all options. The mere presence of a cognitive disorder is not, in itself, sufficient grounds to declare the patient incompetent.

No one definition encompasses legal competency. Concluding whether one is legally competent depends on the application of a balancing test of various factors. Four main factors to be considered are the ability to communicate a choice, to understand the relevant information, to appreciate the nature of the situation and its likely consequences, and to manipulate information rationally:

- § Inability to communicate means that the individual is unable to relay his or her treatment wishes either because of inadequate communication skills, or other circumstances such as being in a coma or a vegetative state.
- § The ability to understand the relevant information does not require that the individual understand the situation entirely but only that the person understands each component of the situation when viewed individually.
- § A patient must understand and accept his or her own ailment and the consequences of different treatments and the option to not treat. Any delusional ideas he or she exhibits regarding other issues do not render the patient incompetent to make decisions pertaining to his or her own treatment.
- § The individual's ability to manipulate information rationally does not require that the he or she reach a particular outcome or conclusion, only that the individual logically "compare [s] the risks and benefits of treatment options."

Caveat

Declaring a person incompetent in any setting raises questions of personal liberty. Rights granted by the constitution are taken very seriously in legal settings, and courts are reluctant to deprive liberties by way of court-appointed guardianship or ordered treatment. When a patient is unable to care for himself or herself and lacks the requisite mental capacity to make informed decisions, a declaration of incompetence may be appropriate so long as it is properly substantiated by medical

documentation of the patient's cognitive and/or physical deficits.

Legal System Involvement

Marc Woodbury-Smith

Department of Psychiatry and Behavioural

Neuroscience, McMaster University, Hamilton, ON, Canada

Institute of Neuroscience, Newcastle University, Newcastle upon Tyne, UK

An individual with an autism spectrum disorder (ASD) may come into contact with the criminal justice system (CJS) as either a victim or perpetrator of a proven or alleged offense as discussed

in detail elsewhere (Dein and Woodbury-Smith 2010, and references therein; Woodbury-Smith 2013). In brief, there is a body of research data, principally case study in nature, which describes individuals with ASD who have engaged in unlawful behavior and among whom a direct association between this behavior and their ASD is claimed. While the prevalence of unlawful behavior in this population is not well understood, and hence a true association in epidemiological terms has not been established, this remains an important topic. Indeed, whether or not there is an association, such individuals are likely to be vulnerable in the CJS, and for the health professional assessing such individuals, a high level of expertise is demanded in order to unravel the relevant risk factors and thereby make treatment recommendations to reduce future risk. Of course, contact with the CJS may not only follow committing illegal acts but also as a result of falling foul to the illegal acts of others, and it is well established that individuals with developmental disabilities, including ASD, are particularly vulnerable in this regard.

With these points in mind, this current chapter will present a clinically focused consideration of the interface between the CJS and ASD. After a discussion of the factors that are most likely to mediate unlawful behavior among those with ASD, based in part on the author's own clinical experience, the assessment process will be described and then management is considered. For a detailed discussion of the background literature, the reader is referred to the accompanying chapter in this volume, ► [Violent/Criminal Behavior in Autism](#) (Woodbury-Smith 2013).

Throughout, the term "unlawful behavior" will be used for any behavior that is inconsistent with the statute of the jurisdiction in which it occurred. Additionally, and in line with DSM-5 (American Psychiatric Association 2013), the term ASD will be used to describe individuals with developmental impairments in the domains of socio-communicative function and a tendency for ritualistic and repetitive patterns of behavior. As such, the previously used diagnostic label "Asperger syndrome" will be subsumed in this category.

Factors Leading to Contact with the Criminal Justice System

As a victim: People with ASD may come into contact with the CJS as victims or perpetrators. While much of the focus on the literature is on individuals with ASD as perpetrators of unlawful behavior (discussed subsequently), there is a real risk that someone with this diagnosis may be a victim. Their vulnerability in this context can be understood as arising from the interaction between a multitude of factors. First, individuals with ASD may struggle with the rules of social interaction and, therefore, may not appreciate fully when others break these rules by, for example, invading their personal space or encouraging them to engage in behavior that may be illegal. This is compounded by the fact that the social vulnerabilities of the person with ASD may often be apparent to others, even if the diagnosis is not. As such, this may be a red flag for individuals with a criminal predilection to take advantage of them. Further, people with ASD may be lonely as a result of their oftentimes social isolation and hence may have a lower threshold for accepting another individual as a friend, even when it is apparent that this other person is treating them badly or taking advantage of them. Finally, people with ASD are probably more likely than others to take people at face value as a result of their mentalizing impairments.

The tendency for rigid and ritualistic patterns of behavior may also lead to situations where the person with ASD becomes a victim. For example, individuals with ASD often have a strong sense of "right" and "wrong" and may voice these to another person who they deem to be in violation of these strong principles. While in general terms this may simply result in argumentative confrontation with others, on occasion the outcome has been more severe. One example from the recent media is of a young male with ASD who confronted a cyclist for illegally riding on the sidewalk, which resulted in the cyclist assaulting him and inflicting a major head injury resulting in his death.

Indeed, it has only been in relatively recent years that people with ASD have been explicitly

taught social skills, and more general life skills, and therefore it is unusual for a child or young adult with ASD to be “street smart.” Negotiating the social milieu in everyday terms involves much more than can be taught didactically in a one-to-one or group setting, and approximating reality invariably requires real-life exposure to social situations. For example, children and young adults need to negotiate the subtleties of everyday communication and the age-specific street vernacular as well as the rules of acceptable social behavior, arguably difficult to achieve in a classroom setting. Consideration of these different factors clearly requires a more ecologically valid treatment approach to social skills.

As a perpetrator: People with ASD may engage in unlawful behavior for a variety of reasons, and, as in the general population, the interaction between these various factors is often complex and the ultimate reason may be not entirely clear. A variety of offenses have been described in the literature (Woodbury-Smith 2013; Mouridsen 2012), although due to publication bias, these probably represent the more severe end of the spectrum. In more general terms, relatively minor transgressions will be more common, such as inappropriately touching someone’s hair in the context of a sensory preoccupation, stealing in the pursuit of a circumscribed interest, or being hostile in the context of bullying (Wing 1997).

Undoubtedly, the social factors that may mediate victimization may also play a role in the perpetration of unlawful behavior by individuals with ASD. The person with ASD may find themselves socially isolated yet have a wish for relationships with others, leading to feelings of loneliness. They may, therefore, seek out relationships, but do so in an inappropriate manner (Murrie et al. 2002; Stokes et al. 2007). This may involve, for example, following a person because of an inability to initiate verbal contact with them. In the extreme, this may become stalking, even when harmful intent is absent. Similarly, a person with ASD may attempt intimacy, either verbally or nonverbally. However, they may have difficulty interpreting the response given by the other person, who, if disinterested, may show irritability or offense on their face or make a sarcastic comment.

These cues, whether they be facial expression, posture, or verbal in nature, would usually act to inhibit ongoing behavior, but in the absence of an ability to “read” such cues, the behavior may continue unabated and ultimately may transgress acceptable boundaries. Of course, the lack of social experience that may coexist with these social vulnerabilities may compound any social difficulties, and the individual may act toward others in a way they have learnt from books or have observed in the visual media.

There are, of course, other factors that may mediate the perpetration of criminal behavior, such as those related to circumscribed patterns of interest or otherwise rigid behavior (Woodbury-Smith et al. 2010) and those related to risk factors in the population at large (Farrington 1995). Three specific problematic behaviors and their mediating factors demand special attention: harassment and stalking, threats to kill, and behavior related to circumscribed patterns of interest.

ASD, social impairment, and stalking: Cases have been described in both the scientific literature and the media of individuals purported to have ASD who have engaged, or are alleged to have engaged, in harassment and stalking behaviors (Barry-Walsh and Mullen 2004; Stokes and Newton 2004). Harassment and stalking describe the persistent approaches of someone toward another, despite clear signals by the victim that these approaches are unwanted. These approaches may involve physically following the person or repeatedly contacting the person by, for example, phone, text, or email or through unwanted gifts. Such behaviors may occasionally be seen among adolescents and adults with ASD, but generally there is no intended threat of harm. The behavior is often driven by the desire for a romantic relationship with the person concerned, yet barriers exist that interfere with this. For example, there may be no easy opportunity for the individual to be physically in close proximity to the other person, particularly if the person with ASD is socially isolated. Moreover, they may not know how to appropriately initiate or sustain conversation that makes it clear that they have romantic aspirations toward this person. Indeed, in one study, the only significant predictor of romantic functioning

among those with ASD was their social functioning (Stokes et al. 2007).

These vulnerabilities are compounded by difficulty interpreting whether the person concerned, through verbal or nonverbal means, is romantically “interested.” Again, in the study of Stokes and colleagues (2007), individuals with ASD were observed to persist for significantly longer periods of time than typical adolescents when they received negative or no response from the person concerned. A tendency for repetitiveness may result in persistent efforts irrespective of the response given to them. Some of these factors have previously been identified among a study of stalkers more generally (Mullen et al. 1999). In particular, intimacy seeking and romantically “incompetent” (their terminology) represented two of several factors mediating stalking behavior in one sample of 145 stalkers referred for forensic evaluation.

ASD, social impairment, and threats to kill:

There is also a risk that individuals with ASD may make threats to kill or otherwise do harm to others, in some cases acting out on such thoughts (Murrie et al. 2002). It is not unusual for a child who is being victimized by, for example, peers to harbor thoughts of wanting to harm these others, and these thoughts are occasionally verbalized, or written down, and hence come to the attention of family, teachers, or health professionals (Wing 1997). It is important to realize that a relatively innocuous snub made by, for example, a passerby in the street may result in a catastrophic reaction among individuals with ASD. Our current social climate is characterized by several high-profile cases of “angry” adolescents and young adults who have harmed their peers, and, therefore, as a result, any threats are understandably taken very seriously, even though among those with ASD the intent to act out on such thoughts may generally not be present. Bullying will be a significant risk factor for such threats, but more general factors will likely include misinterpretation of others’ vocalizations or gestures, a sensitivity to the comments made by others, and difficulty with emotional regulation, such that the distress in these situations is acted on without thinking (or necessarily knowing) the potential consequences.

ASDs and circumscribed interests: The possibility that the nature of a person’s circumscribed patterns of interest may mediate unlawful behavior has been written about widely (Woodbury-Smith et al. 2010; Barry-Walsh and Mullen 2004; Murrie et al. 2002). A number of case studies have been described in the literature alleging a link between the nature of the interest and the unlawful behaviors observed. These include both interests that are not inherently unlawful, but the pursuit of which has resulted in illegal behavior and interests that are violent or involve a violent theme.

Assessment of an Individual with ASD in the Criminal Justice System Setting

In what follows, it will be assumed that the person in question, whether an adolescent or young adult, is a diagnosed individual with ASD who has been referred after alleged unlawful behavior. In situations where a person is suspected of having an ASD, an additional layer of assessment is required, i.e., diagnosis. While diagnosis is discussed elsewhere in this volume, one crucial point to consider is that whatever the age of the suspect, it is vital that an informant supplies relevant developmental information. It is neither appropriate nor diagnostically valid to take a cross-sectional history and base the diagnosis on this. ASD is, by definition, of developmental onset. Moreover, it is also important to realize that socio-communicative difficulties in young adulthood are common, particularly among those in the CJS, and their origin is often multifactorial.

Beyond diagnosis, it may also be useful to undertake a formal neuropsychological assessment (Clare and Woodbury-Smith 2009). This may include an assessment of both general intellectual ability and level of adaptive skills, as well as more specific areas of cognition, such as social cognition, language, and executive function. There are now a number of commercially available established tests for the assessment of cognitive domains such as these, and these tests have demonstrated good reliability and validity properties across specific age ranges and in particular

populations of individuals. A full description of these tests is out the scope of this current chapter, and the reader is referred to appropriate specialized texts for a full description.

The rationale for completing tests such as these is severalfold. First, they allow for the quantification of the exact degree of impairment. Although it is possible during the clinical assessment to identify the areas of vulnerability, and illustrate these with specific examples, it is sometimes difficult to objectively quantify the extent of the impairment, and the degree to which this is different from same age peers. It is also important to characterize the person's areas of relative strength and vulnerability, as this will be relevant when devising treatment strategies. In general terms, areas of strength are "used" as far as possible to develop strategies to address the vulnerabilities. Finally, it is important to gain an understanding of the person's level of functioning, which is usually gleaned from a measure of global intelligence in combination with a measure of adaptive functioning. Discrepancies between intellectual capacity and level of everyday skills are usually the result of other cognitive impairments (such as social cognition).

In addition to the formal assessments, and where appropriate diagnosis, time will be spent interviewing the individual. As with any clinical interview, this will allow the interviewee to give their own account of events as well as the interviewer to explore possible antecedents and contextual factors. In particular, living and employment (or educational) circumstances can be explored, as well as relationships and personal attitudes and beliefs. This also gives the opportunity to ascertain whether there is any evidence of mental health comorbidity, either in the form of additional neurodevelopmental disorders (such as ADHD or specific learning difficulties) or mental illness (such as depression, anxiety, or psychosis). If necessary, a specialist mental health assessment will need to be sought, and additional formal measures can be used such as the *Beck Depression Inventory* (Beck et al. 1996) and/or the *Beck Anxiety Inventory* (Beck et al. 1988).

Information obtained from a clinical interview may be augmented by specific measures related to

sexual knowledge and social networks. Social networks, in particular, may play a key role in both the etiology of problematic behavior and also in rehabilitation and recovery, and so collecting detailed information on this is particularly important. The person's knowledge of relationships can be ascertained using questions from the ADOS-G modules 3 and 4 (Lord et al. 2000), and their understanding of consent and abuse and their more general sexual knowledge (also useful when interviewing alleged victims) can be obtained using the methods of Murphy and O'Callaghan (2004). Finally, information regarding the person's social support network can be facilitated using a scale such as the "Significant Others Scale" (Power et al. 1988).

It is important to realize that the vulnerabilities of the individual with an ASD may not be immediately apparent to criminal justice system workers, particularly if they function intellectually in the typical range (Allen et al. 2008; Browning and Caulfield 2011). Unlike those with global cognitive delays, who may have language limitations or whose facial appearance (or stature) may act as immediate red flags, recognition of a higher functioning individual may be more problematic, oftentimes compounded by the tendency for such individuals to mask or play down their vulnerabilities, wishing to appear "normal." Beyond their recognition, people with ASD may also be vulnerable during the police interview and during the subsequent trial. These issues are discussed in the subsequent sections.

People with ASD and vulnerability during the police interview: It has long been recognized that people with developmental disabilities, including ASD, are vulnerable when being interviewed in the criminal justice system setting (Allen et al. 2008; Browning and Caulfield 2011). People with ASD have difficulties understanding irony, sarcasm, and, more generally, the "unrevealed" meaning of questions and statements and may therefore misinterpret what is being said to them or asked of them. This is compounded by the fact that, their disability may not be immediately apparent to the untrained eye, which may consequently assume an intact understanding. Any peculiarities of behavior on the part of the ASD

suspect may be misinterpreted as purposeful evasion or obstruction to the process of the interview. There are now measures in place to try to raise awareness of ASD among criminal justice workers such that these individuals are recognized as early in the process as possible.

Related concerns include those of acquiescence and suggestibility during the police interview or in the courtroom during the criminal justice process (Maras and Bowler 2012a, b; North et al. 2008). Acquiescence refers to a tendency to agree to what is being asked or said because the person thinks that this is expected of them. Acquiescence is characterized by a wish to please others by saying what they think the other person wants to hear, whether or not it is a true account of reality. This may occur if the interviewee wishes the interview to be over as quickly as possible or may be motivated by a wish simply to be liked by the interviewer. Suggestibility on the other hand is generally employed to describe the uncritical acceptance of information being offered or susceptibility to misleading information and may have a more complex origin. For example, the questioning style of the interviewer (who may use leading or closed questions) may influence the responses given. The types of language used, particularly language that involves the use of metaphor, irony, and sarcasm, may also influence the accuracy of the responses offered. Moreover, poor problem-solving capacity when thinking on one's feet has been hypothesized to result in a greater tendency to rely on immediate linguistic and social cues rather than the person's actual recall of events.

The assessment of acquiescence and suggestibility will determine the extent to which the individual may be vulnerable during the interview. There are established methods to measure these vulnerabilities, perhaps the widest used being the Gudjonsson Suggestibility Scale (Gudjonsson 1984). Interestingly, this scale has been used previously among adults with ASD and failed to find any tendency for acquiescence or suggestibility compared to a matched group (Maras and Bowler 2012b), although conflicting results have also been reported (North et al. 2008). Similarly, children with ASD have also been shown to be no

more acquiescent or suggestible than their peers (McCrory et al. 2007). However, in this study, gist memory was demonstrated to be impaired among those with ASD, and they did rely more on direct questions, showing vulnerability with free recall.

The trial itself may be a stressful experience for an individual with ASD whether they are a witness or a defendant. Specifically, however, fitness to plead and stand trial can be formally assessed using a fairly well-established series of questions:

- Do you know what the police say you have done?
- Do you know the difference between saying "guilty" and "not guilty"?
- What is your lawyer for?
- Can you tell your lawyer your side of things?
- Do you know what it means to say you can object to people on your jury?
- What happens in court?

Management Issues: Overview

For individuals with ASD who are involved in the criminal justice system, there may be an opportunity for diversion into clinical services that offer rehabilitation. This will, of course, depend on the nature of the offense and the availability of services but ultimately rests with the judicial authority. In the real world, many transgressions will be relatively minor, affording the treating team the opportunity to intervene before anything serious happens. In these situations, there are a number of interventions that may be effective at reducing the risk of subsequent behavior of greater severity.

Reducing risk through management of socio-communicative vulnerabilities: Social skills training may be beneficial for rehabilitation. This affords the opportunity for individuals who are otherwise isolated to meet other people, as well as provide a forum to explicitly teach positive social skills and increase awareness of social *faux pas* or otherwise socially inappropriate behavior. The empirical support for social skills training is far from complete, and the efficacy of social groups vis-à-vis explicit social skills training needs further elaboration (for a critical review

of social skills training for children, see, for example, White et al. 2007 and for adults Bishop-Fitzpatrick et al. 2013). One-to-one therapy may be more beneficial for certain individuals, particularly those who are resistant to the group setting or those who have engaged in more serious behavior. There is some indication that one-to-one therapy using cognitive behavior therapy (CBT) may be beneficial at reducing preoccupations with violent and sexual themes (Barry-Walsh and Mullen 2004) as well as reducing the overall severity of the socio-communicative impairments in ASD (Wood et al. 2009).

Reducing risk through facilitating empathy skills: The ability to “read” simple (happy, sad, and so forth) and complex (sarcasm, irony, and flirtation) emotions in others fundamentally mediates our interactions and will arguably play a role in some of the socially inappropriate and unlawful behaviors seen in ASD. Indeed, the ability to empathize in the population at large is widely believed to protect individuals from victimizing others (Miller and Eisenberg 1988), and an inability to recognize emotions in others has been shown to be associated with offending among individuals with psychopathy (Blair 2001) and individuals with ASD (Woodbury-Smith et al. 2005). It seems reasonable to expect, therefore, that by engendering better empathy skills among people with ASD, their risk of unlawful or otherwise inappropriate behavior will be reduced. There are several empathy training programs that are commercially available, including the *Mind Reading* software package for children and adults (Golan and Baron-Cohen 2006) and the *Transporters* package for children (Baron-Cohen et al. 2009), which are useful for improving the ability to recognize emotions in others. Other approaches attempt to develop perspective taking through role play or the use of videotaped scenarios depicting different interpersonal situations.

Reducing risk through management of comorbidities: The frequency of mental health comorbidity and additional developmental diagnoses is particularly high in this population, and the management of these must also be undertaken using appropriate medical, psychological, and social interventions.

Management: Specific Issues

Aggression: The management of aggression requires a clear understanding of the nature, and interaction between, the different predisposing, precipitating, and perpetuating factors in the medical, psychological, and social domains for the episodes of violence observed. This information may then be used to guide treatment. For example, social factors, such as life events, can be managed through the identification of these events and the implementation of support and active therapy where necessary. This may be true of factors such as loss and bereavement, which would require supportive psychotherapy, and for any unanticipated change in the person’s routines and environment, which may require restoration of a mutually agreed routine as far as is possible. Similarly, psychological factors such as poor judgment and problem-solving skills may benefit from executive building strategies (Cicerone et al. 2011); a lack of empathy and poor emotion recognition and “mentalizing” impairments may benefit from cognitive behavior strategies or more explicit techniques to develop emotional awareness of self and others (Golan and Baron-Cohen 2006); and a low tolerance threshold may benefit from anger management (Day et al. 2008). Although medical factors themselves may not play a huge role in mediating aggressive behavior, the medical management of aggression may include psychopharmacological interventions. The effectiveness of different treatment modalities for violent behavior has been reviewed in detail elsewhere (McGuire 2008).

Stalking and unlawful sexual behavior: Since so little is known about the factors that are associated with sexual offending (in broad terms, i.e., including stalking and harassment) in this population, specific treatments are yet to be developed. Stalking and harassment require some specific management strategies as discussed elsewhere (e.g., see Mullen et al. 2001). In particular, there is an immediate requirement to ensure physical distance between the two parties and, once established, to then stop the behavior and prevent its reemergence. If the behavior is driven by a belief that the person reciprocates their desire for

a relationship, then this will require a therapeutic approach with a particular focus on developing skills to interpret the verbal and nonverbal communication of others. If the behavior is principally driven by the desire for a relationship, then an approach that includes sexual and relationship education is warranted. This may be delivered in a group setting as a didactic education exercise and may be facilitated by the use of social stories (Tarnai and Wolfe 2008). There is also a sexual education program specifically designed for adults with ASD (Hénault 2005), which is a 12-session program covering the key areas of sexual knowledge.

Beyond sexual education, for those who have been convicted of sexual offenses, community and inpatient sex offender treatment programs do exist, and in addition to education, these focus on the development of skills through role play and the reduction of risk through aversion therapy. The group-based nature of these programs reduces the risk of denial and minimization, and their cognitive behavioral basis allows cognitive distortions and victim empathy to be developed. These same strategies may be reasonably applied to those with ASD, but including such people in sex offender treatment groups either in the community or in a custodial setting may be inappropriate. In particular, their level of understanding may impact their ability to keep apace with their peers, and so a modified program may be required.

People with ASDs who make threats: The management of people who make threats will depend on the individual circumstances and the assessment of ongoing risk (and risk of escalation). The immediate aim is to reduce the risk of actual harm, and therefore physical distance must be established and maintained between the two parties involved if at all possible. Once the risk of actual harm is reduced, focus can turn to managing the context (e.g., bullying if present) as well as reducing ongoing risk through engagement with the victimizer. This will usually involve teaching executive function (i.e., problem-solving and good judgment) skills to deal with difficult situations and risk reduction through cognitive interviewing that focuses on the potential consequences for the person if they were to do harm to

another. Methods to develop problem-solving and good judgment skills originate principally in the rehabilitation of individuals with acquired brain injury and are discussed in detail elsewhere (see, e.g., Cicerone et al. 2011, and references therein).

Circumscribed interests and unlawful behavior: Reducing the risk of unlawful behavior in the context of a person's circumscribed interest requires consideration of the purpose of the interest for the person concerned. Notably, interests often maintain self-esteem, and to simply introduce strategies to extinguish a person's interest may make matters worse. Instead, measures must be taken to "contain" the interest within acceptable boundaries and "mold" the interest into something more appropriate. For example, a preoccupation with firefighters that results in repetitively calling 911 can be replaced with books or DVDs containing scenes of firefighters in action. Similarly, for those with an interest in a potentially violent theme (such as weapons or infamous historical figures such as Adolf Hitler), the focus will be on "containing" the interest within acceptable boundaries (such as discouraging talking with others about the interest) as well as attempts to replace the interest with opportunities for an "ordinary life."

Conclusions

This chapter has considered some of the factors that may lead someone with an ASD to come into contact with the criminal justice system and then presented a discussion of the assessment and management of such individuals. There are clearly a number of different factors that may be involved, singularly or in combination, and the only way to fully realize these is through detailed assessment. One of the issues that remain, however, is the paucity of available specialist treatment programs for this population, either in the community, in a mental health inpatient setting, or in the criminal justice system. Paralleling this is the limited availability of research evidence outside of case studies or small case series. Ultimately, service development will require dialogue between social and mental health services and the criminal justice system.

Leigh Disease

Anamiguel Pomaes-Ramos

Yale Child Study Center, New Haven, CT, USA

Synonyms

Infantile subacute necrotizing encephalopathy;
Juvenile subacute necrotizing encephalopathy;

Leigh necrotizing encephalopathy; Leigh syndrome; Leigh's disease; SNE; Subacute necrotizing encephalomyelopathy; Subacute necrotizing encephalopathy

Definition

Leigh disease is a rare neurometabolic disorder characterized by a progressive loss of motor and cognitive abilities. It is estimated to affect 1 in 40,000 newborns, with a higher prevalence in Quebec, Canada (approximately 1 in 2000 newborns) and on the Faroe Islands (approximately 1 in 1700 newborns). The onset of symptoms typically occurs during infancy; although in rare cases, onset occurs during adolescence or adulthood.

The first noticeable signs for Leigh disease are gastrointestinal symptoms (e.g., nausea and recurrent vomiting and diarrhea) and failure to thrive. Additionally, affected individuals may develop severe movement difficulties and experience motor regressions. Symptoms may include: difficulty swallowing (i.e., dysphagia), difficulty coordinating movement (i.e., ataxia), decreased muscle tone (i.e., hypotonia), involuntary muscle contractions (i.e., dystonia), numbness (i.e., peripheral neuropathy), and difficulty articulating speech (i.e., dysarthria).

If the onset of Leigh disease occurs during early childhood, symptoms develop rapidly and lead to the deterioration of the central nervous system. As symptoms become more advanced, lactic acid levels may increase in the blood, brain, urine, or the cerebrospinal fluid. This could cause respiratory, heart, kidney, and further motor impairments. Individuals may also present breathing problems, such as abnormal breathing patterns (i.e., Cheyne-Stokes), temporary cessation of breathing (i.e., apnea), or labored breathing (i.e., dyspnea). This condition may also cause thickening of heart muscle cell (i.e., hypertrophic cardiomyopathy) and degeneration of the optic nerve and extra ocular muscles (i.e., optic atrophy and ophthalmoparesis).

Leigh disease can be caused by over 75 mutations in the nuclear DNA (nDNA)

and – in 20% of cases – in the mitochondrial DNA (mtDNA). These mutations predominantly occur in genes that influence energy production. Specifically, mutations disrupt the protein complexes involved in oxidative phosphorylation and the pyruvate dehydrogenase complex – these protein complexes drive the production of cellular energy (ATP). The reduction in cellular energy disrupts the functioning of the cell; as a result, this deteriorates tissue in the central nervous system and vital organs that require high levels ATP for normal functioning. In rare cases, individuals with autism may also have a mitochondrial disease. This small subset of individuals present with mutations in nDNA and mtDNA that disrupt oxidative phosphorylation. However, there is limited research examining the possible association between autism spectrum disorder and mitochondrial disease.

Individuals with Leigh disease may inherit the condition through different patterns, such as autosomal recessive, mitochondrial inheritance, and X-linked recessive patterns. Autosomal recessive is the most common inheritance pattern. Affected individuals inherit a copy of the mutated gene from each parent. For the X-linked recessive pattern, the mutated gene is located on the X-chromosome. Males with Leigh disease only need one copy of the mutated gene, while females need two altered copies of the gene to have the disease. These inheritance patterns apply to individuals who have mutations in the nDNA. Mutations of genes in mtDNA are mostly inherited through mitochondrial inheritance (i.e., maternal inheritance).

Leigh disease can be diagnosed through laboratory testing, clinical evaluation, neuroimaging, and molecular genetic testing. Prognosis for this condition is poor. Due to the heterogeneity of symptoms, a comprehensive plan is created to address each specific symptom.

Leisure Participation Patterns for School-Age Youth with Autism

Karen Ratcliff and Claudia Hilton
Occupational Therapy Department, University of
Texas Medical Branch, Galveston, TX, USA

Definition

Participation in leisure is an integral part of the human experience. Leisure activities are varied,

and participation in leisure is associated with quality of life (QoL) and physical and mental well-being (Potvin et al. 2013). Billstedt et al. (2011) suggested participation in leisure activities as a possible proxy for QoL in individuals with autism spectrum disorders (ASD). Leisure is defined as time spent on activities that are not for survival, work, or sleep (Zeigler 1965). Recreation is defined as engaging in leisure activities for the purpose of pleasure, education, or satisfaction (Zeigler 1965). Across participation literature, the line between leisure and recreation activities is blurry, and differentiating activities between the two categories is not consistent.

Current Knowledge

Participation in leisure provides psychological, spiritual, social, and cultural meaning and value to the human experience (Iwasaki et al. 2018). Iwasaki et al. (2018) describe the role of leisure as providing a joyful, connected, discovered, composed, and empowered life. The authors explain that leisure reduces suffering and provides a joy by the positive emotions elicited. Leisure provides connection via routes of social connectedness and connectedness with nature, religion, and culture. Leisure provides the opportunity to uncover and promote an individual's special talents and characteristics. Leisure allows individuals the opportunities to control their pace and be flexible, promoting control and a sense of autonomy. Finally, engagement in leisure provides healing and stress coping for individuals. These benefits of leisure promote QoL and allow individuals to flourish.

Children with autism spectrum disorders (ASD) report lower QoL (Lin 2014), decreased participation in recreation and leisure (Hilton et al. 2008), and decreased flourishing (Hilton et al. 2019), particularly as they age into adolescence (Ratcliff et al. 2018). Individuals with ASD demonstrate different participation patterns than typically developing individuals and lack regular participation in recreational activities, contributing to poorer QoL (Billstedt et al.

2011). Participation in leisure activities promotes physical and mental health for individuals.

Children, adolescents, and adults with ASD demonstrate poorer mental health with high incidence of comorbidities, such as depression and anxiety (Schall and McDonough 2010), and decreased physical health (Hilton et al. 2014). Children with ASD are at risk for decreased participation in recreational activities (Kaljača et al. 2019). Lack of participation in leisure for individuals with ASD has negative impacts, including poorer mental health, decreased physical fitness, decreased QoL, and inability to flourish. This entry will present the patterns of participation in leisure across participation categories for children with ASD and recommendations for improving participation for children with ASD.

Participation preferences of children with ASD. Several studies have addressed the leisure participation preferences of children with ASD. In one study, the top ten preferences were playing on the computer or video games, watching TV or a rented movie, visiting others, playing with toys, swimming, doing crafts, drawing or coloring, going to a party, playing with pets, playing board or card games, and going to the movies (Eversole et al. 2016). Potvin et al. (2013) had similar findings that children with ASD enjoyed playing computer or video games, watching TV or rented movie, reading, going to a party, visiting others, doing homework, playing with things, shopping, doing crafts, talking on the phone, hanging out, and playing board or card games. The activities enjoyed less by children with ASD from typical peers include physical activities and formal activities (Potvin et al. 2013). An activity that was reported to be enjoyed more was swimming (Eversole et al. 2016).

Participation patterns of children with ASD. Across leisure participation studies, subtypes of activities are inconsistent. They often categorize activities into types of participation based on the types of assessments performed (Hilton et al. 2008; Little et al. 2014; Potvin et al. 2013; Solish et al. 2010). The general trend toward agreement of categories seems to group them into *physical*, *social*, *self-improvement*, and *home-based solitary* activities.

Participation in physical activity. Studies consistently concur that individuals with ASD participate in less physical activity than same-age peers. Several studies have compared the total amount of time spent in moderate and vigorous physical activities. In a study of Irish children, 70.1% of the children with ASD participated in less than 5 days of moderate to vigorous physical activity in a 2-week period compared to 23.9% of the control group (Healy et al. 2017). Stanish et al. (2017) found that adolescents with ASD spent less time in moderate to vigorous physical activity, fewer of them met the daily Physical Activity Guidelines for Americans (USDHHS, 2008), and they participated in fewer physical activities compared to same-age peers. Memari et al. (2015) had similar findings that only 10% of the children with ASD in their study were physically active. McCoy et al. (2016) found that adolescents with ASD were less likely to participate in physical activity compared to same-age peers using a nationally representative dataset.

Limited participation in physical activities has ramifications on physical health, including obesity, high BMI, diabetes, and cardiac health. In a study examining the relationship between physical activity, BMI, and arterial stiffness, children with ASD demonstrated decreased physical activity, higher BMI, and increased arterial stiffness, putting them at greater risk for cardiovascular disease (Heffernan et al. 2018). In another study, children with ASD were 40% more likely to be obese than unaffected children (Lawson and Foster 2016). A study of a nationally representative dataset found that adolescents with ASD were 27% more likely to be overweight and 72% more likely to be obese than typically developing adolescents (McCoy et al. 2016). In the same data set, those adolescents classified as having mild ASD were 56% less likely to engage in regular physical activity, and those classified as having severe ASD were 70% less likely to participate in regular physical activity than the unaffected adolescents. Decreased participation in physical activity results in increased health risks for these children with ASD.

In studies examining participation in formal, organized physical activities, children with ASD

participate in fewer of them compared to their same-age peers. Activities defined as formal physical activities include sports, sports lessons, playing on a team, bicycling, individual physical activity, martial arts, and track and field. Potvin et al. (2013) compared 7–13-year-olds with high-functioning autism and a peer control group and found that the ASD group participated in fewer types of physical activities. Healy et al. (2017) found that children with ASD participated in fewer sports and extracurricular activities than typically developing peers, particularly physical activities with coaches. Taheri et al. (2016), similarly, found that children with ASD and intellectual disability (ID) participated on fewer sports teams.

Participation in organized, formal physical activities is a significant predictor of sports participation and physical fitness activities in young adulthood (Perkins et al. 2004). Additionally, the greater diversity of participation in sport activities predicts better health, higher education levels, and higher activity levels in adulthood (Mäkelä et al. 2016). The decreased participation and lack of diversity that children and adolescents with ASD experience have long-term implications for health and wellness as adults.

Participation in social activities. Participation in social activities consists of those that involve participation with friends; community activities, such as clubs, organizations, volunteering, and worship and religious activities; and organized activities, such as lessons, team sports, and classes. Kaljača et al. (2019) found that children with ASD participate in significantly fewer social activities than typically developing peers. Social activities with particularly limited participation by children with ASD were playing games, birthday parties, playing at a friend's home, having a sleepover, talking on the phone and computer, going to the movies, and going out for meals.

Solish et al. (2010) also found that children with ASD participated in fewer social activities compared to typically developing peers. In a study comparing the social participation of typically developing children, children with ID, and children with ASD and ID, aged 3–19, Taheri et al.

(2016) found that the ID and ASD with ID groups participated in fewer social activities including unstructured play, social outings, special occasions, and community activities. Compared to the ID-only group, the ASD with ID group participated even less in social activities, such as special occasions with friends. In another study, Memari et al. (2015) found that children with ASD spent more time in solitary play than social play.

In a study examining the social participation of young adults with ASD, the characteristics of those with decreased social participation were more likely to be male, from the highest income category, have a higher rate of conversational impairment, live at home with parents, never see friends, never get calls from friends, and never get invited to activities with others (Orsmond et al. 2013). These are consistent with finding from another study (Orsmond et al. 2004), finding that 46.4% of 235 adolescents with ASD reported no peer relationships. Similarly, Taheri et al. (2016) found that children with ASD had significantly fewer school friends and other friends than their typically developing peers and the friendships they did have were of poorer quality.

Decreased social participation is associated with poorer mental health outcomes, such as depression, loneliness, and anxiety. Batsika and Sharpley (2015) found that feelings of depression were associated with lack of self-confidence in social interactions. In a study examining the mediators between autism phenotype and depressive symptomology, social problem-solving was identified as a mediator, along with poor social interactions, perceived social awkwardness, and social anxiety (Jackson and Dritschel 2016). In a similar light, Ratcliffe et al. (2015) found that social skills explained over 40% of the variance in mental health difficulties based on teacher and parent scores for children with ASD. These social difficulties result in limited participation in leisure activities for individuals with ASD from childhood through adulthood. Bohnert et al. (2016) found that decreased participation in organized activity was associated with greater social impairment, depressive symptoms, and loneliness.

Myers et al. (2015) found that higher cognitive function and access to case management

improved social participation, whereas behavioral and communication difficulties were associated with social isolation. Taylor et al. (2016) looked at the relationship from changes in high school to out of high school in structured and unstructured social participation and found that structured activities declined with the transition for most participants and unstructured activities increased for those that were involved in more structured activities during high school. Additionally, those individuals with more internalizing behaviors in high school demonstrated more social isolation outside of high school. Increasing opportunities for participation in social activities improved QoL and decreased loneliness for individuals with ASD. There is a great need for social participation and social activities for individuals with ASD. Jantz (2011) found that ASD support groups provided opportunities for social interaction, information, advice, and structure and resulted in decreased loneliness.

Home-based solitary leisure activities. Consistently across studies, participation in home-based solitary leisure is the area that children with ASD participate in most similarly to their unaffected peers. In addition to swimming, it is an area in which they participate in and enjoy the most. In studies comparing sedentary behaviors between children with ASD and typically developing peers, the ASD groups spend significantly more time in computer use, television, and screen time (Healy et al. 2017; Must et al. 2014; Ratcliff et al. 2018). The typically developing children spend more time doing crafts and playing board games than did the children with ASD. Another study found that children with ASD engaged in significantly more time than typically developing children watching TV and playing video games to a level that became problematic, such as wanting to play video games more than interacting with family and friends and spending a lot of time thinking about playing video games (Mazurek and Wenstrup 2013). Additionally, these children spent less time in socially interactive video games or social media than the typical children, demonstrating that they were less involved and were uninterested in the social outlets associated with social media and video games.

High level of television watching negatively impacts physical fitness levels in childhood and is predictive of poor fitness in adulthood, with adult obesity 1.25 times more likely in adulthood and poor fitness 1.4 times more likely with each mean hour of television viewing during the week as a child (Landhuis et al. 2012).

Barriers to Leisure Participation

Studies report numerous barriers to participation in physical activity for children with ASD. Children with ASD participate in fewer formal, organized physical activities because of social and motoric difficulties (Memari et al. 2015; Stanish et al. 2015). Among the barriers cited were the children's preference to engage in technology-based activity, their difficulty with motor skills, their lack of social support, and their physical or community environments that were not conducive to their participation (Obrunsnikova and Cavalier 2011). Barriers identified by a qualitative study that interviewed youth with ASD, parents of youth with ASD, and service providers were limited understanding of social situations, maladaptive behaviors, and lack of social skills training programs for older children (Ghanouni et al. 2019). In a study examining the parental perceptions of barriers to physical activity, sensory sensitivities, gross motor deficits, behavioral outbursts, and difficulties in social situations, which impacted participation in team sports and group activities, were identified (Nichols et al. 2019). Must et al. (2015) also examined parent perceptions of barriers and reported that many children with ASD required too much supervision compared to typical peers, that supervising adults lack skills needed to include the children with ASD, and that their children have few friends, so are not invited to participate in many activities.

Future Directions

Potential solutions to increase leisure participation by children with ASD come from several directions. Parents are vital in keeping children

and adolescents with ASD physically active. Findings indicate that creating a physical activity routine and making it a habit improve regular participation in physical activity (Nichols et al. 2019). Supports, training, and respite programs for parents are effective interventions to enable their ability to promote successful behaviors of children with ASD. Social skills training has also shown effectiveness for improving social participation for individuals with ASD (Garcia-Villamizar and Dattilo 2010).

Health and public policies to adjust community environments to make them more inclusive and supportive are needed to increase participation in recreation and leisure by children with ASD. Research findings have shown that when physical activity programs are available, individuals with ASD are more physically active (Nichols et al. 2019). Funding is also needed to support programs that address participation in recreation and leisure for individuals with ASD. Community programs that teach social skills and encourage active engagement in areas of interest for children with ASD are needed to encourage participation in recreation and leisure. Programs that educate the public on how to best deal with those on the spectrum can be helpful in building supportive community environments. This knowledge is also important for public servants, such as police officers, who need to know that atypical responses should not always be interpreted as threatening or dangerous.

Leiter-R

Description

The Leiter International Performance Scale-Revised (Leiter-R; Roid and Miller 1997) is a nonverbal measure of intellectual functioning normed for individuals between the ages of 2 years 0 months and 20 years 11 months. The tasks on the Leiter-R, which generally require a matching or pointing response, are meant to be self-explanatory and require minimal pantomimed instructions. Leiter-R materials consist of stimulus easels, cards, and foam shapes. The test takes about 90 min to administer.

The Leiter-R includes both visualization and reasoning (VR) and attention and memory (AM) batteries, comprised of 10 subtests each, though not all subtests are administered to all age groups. The VR and AM batteries may be administered separately or together, depending on the clinical need.

The VR battery is used to obtain IQ estimates and assesses traditional constructs of intelligence including nonverbal reasoning, visualization, and problem solving. The composite scores of the VR battery include a brief IQ screener (ages 2–20 years), full-scale IQ (2–20 years), fluid reasoning (2–20 years), fundamental visualization (2–5 years), and spatial visualization (11–20 years). The VR battery also offers an optional criterion-referenced metric called the Growth Score. The Growth Score is not age standardized or norm referenced and may be used to track change over several years (Roid et al. 2009). VR subtests and their primary tasks are listed in Table 1.

The AM battery measures nonverbal attention and memory function and is often used to assess the effects of attention deficit/hyperactivity disorder (ADHD) or learning disorders. The composite scores derived from the AM battery are memory screener (ages 2–20 years), associative memory (6–20 years), memory span (6–20 years), attention (6–20 years), memory process (6–20 years), and recognition memory (4–10 years). AM subtests and their primary tasks are listed in Table 2.

The Leiter-R also includes four optional social-emotional scales, (1) examiner, (2) parent, (3) self, and (4) teacher. Items are scored on a scale of 0 (rarely/never) to 3 (usually/always). These

Leiter International Performance Scale-Revised (Leiter-R), Table 1 VR battery subtest descriptions

Subtest	Summary of nature of task
Figure ground	Location of a stimulus, presented on a card, embedded within a more complex picture
Design analogies	Completion of abstract analogies presented in matrix form; the more difficult items require mental rotation of objects
Form completion	Mental assembly of a fragmented picture to form a whole
Matching	Matching a visual stimulus with an identical design
Sequential order	Selecting the correct picture or figure to complete a logical progression of stimuli; selection of related stimuli which progress in a corresponding order
Repeated patterns	Identifying the correct stimulus to complete a pictorial or figural pattern
Picture context	Identifying an object that has been removed from a complex display by using contextual clues
Classification	Categorizing stimuli based on salient characteristics such as color or shape
Paper folding	Mentally “folding” an object displayed in two dimensions and selecting the finished product from a lineup
Figure rotation	Identifying a two- or three-dimensional object that has been rotated

scales, which tap behaviors like inattention, hyperactivity, sociability, and mood regulation, are meant to serve as adjunct to the cognitive assessment and to aid in the interpretation of the testing results.

Historical Background

While a graduate student in California, Russell Leiter developed a scale of intelligence that was meant to be free of cultural bias, and this scale was later refined with Hawaiian children. Dr. Leiter was awarded a National Research Council grant to support the standardization of the Leiter Scale, which was published for the first time in 1934. The Leiter has gone through several revisions by Dr. Leiter and others. Although the content,

Leiter International Performance Scale-Revised (Leiter-R), Table 2 AM battery subtest descriptions

Subtest	Summary of nature of the task
Associated pairs	Observing pairs of pictured objects for 5–10 s, then remembering meaningful and non-meaningful associations
Immediate recognition	Discriminating between present and absent objects following the brief presentation and removal of a stimulus array
Forward memory	Recalling the sequence of objects pointed to by the examiner
Attention sustained	Completing clerical tasks such as finding and crossing out all squares within an array of geometric shapes; the tasks are more complex for more advanced individuals
Reverse memory	Recalling the sequence of objects pointed to by the examiner in reverse order
Visual coding	Identifying, from a key, the appropriate stimulus to complete a pair
Spatial memory	Recalling the location of a matrix array of stimulus cards after a brief presentation
Delayed pairs	Recalling the pairs presented in the first subtest, associated pairs, after approximately 30 min
Delayed recognition	Recognizing the objects present in the immediate recognition subtest after approximately 30 min
Attention divided	Attending to a task that requires identification of a target while also learning a card-sorting task

procedures, or norms of the test had not changed in any substantial way since the 1948 version, materials were copyrighted in 1979. These versions of the Leiter (1979) and the Leiter-R (Roid and Miller 1997) are the most recent. Although it was valuable for use in children with communication disabilities, the Leiter (1979) had several shortcomings. The psychometric characteristics of the test were weak, owing to inadequate standardization and norms for children aged 5–17 years last updated in the 1940s (Shah and Holmes 1985). The Leiter also utilized a ratio IQ, which is no longer considered an adequate representation of intellectual functioning. The constructs measured by the Leiter vary widely and are represented by few items. In contrast, the

Leiter-R was developed using several prominent theories of intelligence, and has updated norms and a more sophisticated psychometric profile. One study has shown the full-scale IQ scores on the Leiter and Leiter-R to be highly correlated in children with autism spectrum disorders (ASD) (Tsatsanis et al. 2003). However, because the content of the tests is different, the tests may not be considered as clinically interchangeable.

Psychometric Data

The Leiter-R VR battery standardization sample consisted of 1,719 typically developing individuals aged 2 years 0 months to 20 years 11 months. The sample was stratified by race, ethnicity, and socioeconomic status according to the 1993 US Census. A subset of 763 children were also administered the AM battery. Eleven special criterion groups were examined with the Leiter-R, including intellectual disability ($n = 123$), ADHD ($n = 112$), and severe speech/language impairment ($n = 98$), but not ASD. These criterion groups were not included in the standardization sample.

In the standardization sample, test reliability was established with internal consistency, test-retest, and inter-rater reliability. Average internal consistency for the subtests ranged from 0.75 to 0.90 for the VR battery and from 0.67 to 0.87 for the AM battery. Composite reliabilities ranged from 0.88 to 0.93 for the VR battery and from 0.75 to 0.93 for the AM battery. Of note was the higher reliability of the full-scale IQ (range 0.91–0.93 for the three age groups) relative to the brief IQ screener (range 0.88–0.90). The standard error of measurement was 4.24 for the full-scale IQ on the VR battery and ranged from 4.74 to 6.71 for AM composites. AM subscales were generally less stable across retesting than the VR subscales.

Validity data, including comparison to the original Leiter and other common IQ tests, supported the proposed use and interpretations of the Leiter-R for typically developing populations. The Leiter brief and full-scale IQ scores correlated highly ($r > 0.85$) with scores from the Weschler

Intelligence Scale for Children-Third Edition. Classification accuracy for cognitive delay ($n = 120$) was good, sensitivity (correctly identified as cognitive delay) was 84.2, and the specificity (correctly identified as typical) was 97.3.

The Leiter-R has been examined independently in two samples with ASD. Tsatsanis et al. (2003) found that the Leiter-R had good concurrent validity with the original Leiter in a sample of children with autism aged 4–16 years. Kuschner et al. (2007) examined the cognitive profiles of 16 children with ASDs aged 3.5–5.5 years. A distinct pattern emerged of relative strengths on figure ground and form completion with relative weaknesses on repeated patterns and sequential order. Differences on figure ground, form completion, and repeated patterns were specific to the ASD group, as they were not found in the typically developing or developmental disability comparison groups.

Although the psychometric properties of the Leiter-R have not been well studied in children with ASDs, there is agreement that the test is appropriate for the population (Tsatsanis et al. 2003).

Clinical Uses

The Leiter-R was designed for a wide variety of user groups; although most commonly used by psychologists, it is appropriate for use by speech and language pathologists, educational diagnosticians, and special educators, among others. The AM battery may be especially relevant to professionals concerned with ADHD symptoms or learning disorders. As with other tests of intelligence, interpretation requires advanced training.

Some considerations are warranted when the test is used for people with ASDs (Tsatsanis et al. 2003). Given the limited eye contact and joint attention skills of populations with autism, brief verbal cues (e.g., “touch” or “point”) and hand-over-hand guidance during teaching trials may be required. The Leiter-R allows for three teaching trials, which may be inadequate for some children with ASDs.

The Leiter-R has several features that may be advantageous for individuals with ASDs. The

nonverbal nature of the test minimizes the need for producing or understanding speech. Procedures for each of the subtests are very similar, minimizing the need for set shifts. Finally, nearly all of the tasks are untimed.

Due to these reasons, the Leiter-R has become especially popular in the assessment of children with developmental disabilities and ASDs in both clinical and research settings (Hooper et al. 2000; Tsatsanis et al. 2003). Given its popularity, it is important to note that the Leiter-R should not be seen as a direct measure of general intellectual ability, since it primarily measures nonverbal skills (Klin et al. 2005). Rather, it is to be used as an *estimation* of general intelligence (Campbell et al. 2008). Despite few psychometric data in this population, the Leiter-R is now widely considered to be an acceptable instrument for the cognitive assessment of children with ASDs to whom traditional tests of intelligence may not be applicable.

Letter of Intent

Annemarie M. Kelly and Christina N. Marsack-Topolewski
College of Health and Human Services, Eastern Michigan University, Ypsilanti, MI, USA

Definition

A letter of intent (LOI) is a document with personalized information about how to provide care and support for a specific individual with disabilities (hereinafter the “beneficiary” of the LOI) (Garner 2019). A primary caregiver or caregiver group can author an LOI to document the essential knowledge that others should have when assisting a beneficiary in the future. Well-designed LOIs provide meaningful insight into all preferences, needs, and plans concerning a beneficiary’s prospective care. Information summaries within an LOI typically focus on three key subject areas: daily living, healthcare and personal wellness, and finance and property management.

Principles of a Letter of Intent

An LOI can be a useful special needs planning tool for individuals with autism spectrum disorder (ASD) and their close caregivers, often a parent, guardian, family member, or friend. In LOI matters, an individual with disabilities who receives care is also commonly referred to as a “beneficiary” of an LOI. Importantly, LOIs are not legally binding documents and should not be confused with formal contracts agreements or wills. A caregiver’s desires and plans for an individual with disabilities can be judicially enforced through official instruments from contract, trust, estate, and tax law. The design of an LOI should complement these binding instruments.

An LOI serves as an informational addendum to binding legal instruments (Andersen and Gary 2018). LOIs often are used in the special needs planning process as unofficial guidance for the following items: power of attorney (healthcare

and finance/property), guardianship appointments, conservatorship appointments, special needs trusts, ABLE accounts, deeds, and wills (Lauderdale and Huston 2012). Generally, the purpose of an LOI is to collect knowledge about a beneficiary from longtime caregivers who are well-acquainted with and well-informed about the individuals' personal, medical, and financial needs.

The contents of an LOI should cover the beneficiary's unique interests, dislikes, needs, strengths, and challenges. A caregiver's advice and directions in an LOI can help others deliver the same quality care and assistance in the future. The goals of an LOI are twofold: (1) to communicate loved ones' intentions about the types of care that a beneficiary should receive in the future and (2) to record specific details about how others should approach certain care tasks (Tencza and Forsythe 2019). From a design perspective, the details of an LOI should be organized into neat categories with clear headings so that the content can be easily understood and reviewed by other people. An LOI is particularly useful to share a caregiver's wishes and acumen when the caregiver is no longer able to provide assistance (Walker and Hutchinson 2019; see also Krakovich et al. 2016).

Letter of Intent Content

LOIs can be designed as collections of helpful suggestions and recommended best practices to care for an individual with disabilities. LOIs should contain practical insights regarding the individual's skills, challenges, and day-to-day activities. They can also include recommendations on how to approach any known or anticipated concerns. If a legal dispute arises regarding ambiguous wording or conflicting phrases within any legal contract, a court may analyze an LOI as evidence of what the parties intended when entering into the agreement. In these instances, an LOI may help a judge to decide whether the law prescribes a remedy for the lawsuit according to principles of fairness and equity.

An LOI should cover vital details about what works well for the individual in all of the major areas of his or her life. These topics include, but are not limited to, the beneficiary's close friends and family, education, employment, socialization, religion, and medical care (Table 1). Each topic within the LOI should discuss the beneficiary's past history, current status, and future plans or goals (Burke et al. 2018). Moreover, each LOI topic should list the full names of all associated individuals and their contact information with current addresses, phone numbers, and email addresses. Other useful material may include answers to the following questions in the LOI's Family Members and Friends of the Beneficiary Section: (1) Which ones are emotionally closest to the person? and (2) Which ones are geographically closest to the person? (Lindahl et al. 2019).

In the General Information Section of an LOI, authors should organize facts about the LOI beneficiary's marital status, spouse, citizenship status, languages spoken, date of birth, and place of birth. The Personal Preferences Section of an LOI can be especially useful for future caregivers and should encompass the following details: social activities that the beneficiary enjoys, hobbies, favorite foods, beloved locations, and preferred music types/artists (Leung et al. 2016). If the beneficiary has religious or spiritual preferences, it can be helpful to explain whether he or she adheres to a particular religion or attends a local place of worship.

An LOI should also encapsulate the beneficiary's financial, tax, and legal plans. The Special Needs Plan Section should list all associated names and contact information (e.g., preferred attorney, law firm, financial planner, and tax advisor). Ideally, an LOI will contain a summary of the short- and long-term goals for gathering and maintaining funds to support the beneficiary. It should address questions like the following: (1) Does the beneficiary have a legal guardian, conservator, power of attorney, trustee, or estate executor? (2) If he or she should require such assistance in the future, do you know of any

Letter of Intent, Table 1 Key information to include in a letter of intent for future caregivers

Item number	Information category
1	General information about the letter of intent beneficiary
2	General information about the letter of intent author(s)
3	Family members and friends of the letter of intent beneficiary
4	Past and present caregivers
5	Summary of special needs plan (short- and long-term goals for gathering and maintaining funds to support the letter of intent beneficiary)
6	Attorney, financial advisor, and tax advisor for estate and special needs planning
7	Guardianship or conservatorship appointments
8	Trusts and trustees
9	Power of attorney
10	ABLE savings account (also known as a 529A account) and all associated online account password and log-in details
11	Estate executor
12	Advocates
13	Letter of intent beneficiary's clothing size numbers
14	Letter of intent beneficiary's education history
15	Letter of intent beneficiary's employment and/or volunteer work history
16	Past and current residences and living situation preferences
17	Personal preferences, likes, and dislikes
18	Religious and/or spiritual preferences
19	Medical care history
20	Individual functional abilities (strengths and weaknesses)
21	Behavior management therapies and regimens
22	Assistive technology (mobility devices and commonly used items)
23	Orthotics and prosthetics
24	Insurance (primary and supplemental) and/or government benefits (including Medicaid, Medicare, Social Security Disability Insurance (SSDI), and/or Social Security Retirement Insurance (SSRI))
25	End-of-life arrangements and wishes for final remains

individuals who might excel in these in roles? and (3) Does the beneficiary have an ABLE account or any other financial holdings? All in all, the LOI should serve as a roadmap that outlines the contents of much longer official documents (see, e.g., Hershey et al. 2015, discussing how to use a letter of intent to guide a special needs planning trustee).

In the Medical Care History Section of the LOI, authors should include any other information that could help future caregivers to provide a beneficiary with the best possible care. Many LOIs contain a directory of a beneficiary's physicians and other healthcare professionals. They also usually record a summary of the beneficiary's personal health history (conditions, treatments, surgeries, accidents, and hospitalizations). An LOI should state any insurance deductibles and out-of-pocket expenses for healthcare services and goods. An LOI can recommend specific therapeutic programs and educators who have proven especially successful in working with the beneficiary in the past. It is common for an LOI to confirm which particular assistive technology products and resources are utilized by the beneficiary (U.S. National Institute on Disability Independent Living, and Rehabilitation Research 2020). Additionally, LOI authors should consider reporting their knowledge about "individual functional abilities," which can be sorted into three primary categories of strengths and weaknesses: conceptual, social, and practical (Leung et al. 2016; see also Mahdi et al. 2018) (Table 2).

If an LOI document is particularly lengthy, it can be helpful to add subject headings to organize the information in the same manner as book chapter titles. As a best practice, an LOI's author should place the LOI with all other relevant legal and personal documents concerning the beneficiary. These include all medical records, legal instruments, and financial records (Arbaje 2020) (Table 3). LOI creators can also consider organizing an LOI and its attachments using page numbers or bates numbers with a table of contents.

Letter of Intent, Table 2 Caregiver insights on individual functional ability to document in a letter of intent

Individual’s conceptual strengths and weaknesses	Individual’s social strengths and weaknesses	Individual’s practical strengths and weaknesses
• Reasoning/problem-solving Processing speed • Short- and long-term memory • Expressive language • Receptive language (ability to understand communications) • Literacy • Education • Overall knowledge • Learning	• Communication skills • Social judgment • Ability to understand and follow social queues and nuances • Ability to understand and follow rules • Ability to make and keep friendships	• Activities of daily living for personal care • Home care and financial management tasks • Responsibilities • Organizing tasks • Instances where third-party assistance is usually needed • Instances where assistive technology or other goods are helpful

Updating and Distributing a Letter of Intent

To confirm when a document was last updated, most LOI authors sign and date their LOIs. Special needs planning experts strongly recommend that caregivers review the summaries and lists within an LOI annually – the document must be regularly revised and updated to reflect changes in the beneficiary’s life. Russell and Grant (2010) offer the following guidance for parents who are writing an LOI for their children:

Your major concern [in writing an LOI] is to make sure that your child will have a happy and meaningful life. Write clearly enough so that anyone who reads the letter in the future will understand exactly what you meant. . . Each year you should take out the letter and review it to make sure it remains current. Occasionally there will be a significant change in your child’s life, such as a new residential placement or a bad reaction to medication, and the letter should be revised immediately if any such change occurs.

An LOI can be typed or handwritten. It is a best practice consider providing copies of an LOI document to the following individuals: appointed guardian or conservator, power of attorney, trustee, estate executor, and legal counsel for the beneficiary. Some caregivers choose to give LOI copies to close friends, family members, or others who may need to know its details (Heller and Kramer 2009). Each year, all stakeholders should receive a copy of the most recent version of the LOI and its attached documents.

Letter of Intent, Table 3 Official documents to attach with a letter of intent

1. Insurance forms related to healthcare services and goods
2. Healthcare power of attorney (also called medical power of attorney)
3. Power of attorney (finance and property)
4. Do-not-resuscitate (DNR) order
5. Trust documentation
6. Court order for guardianship or conservatorship
7. ABLE savings account (529A) forms and online password and account sign-in information
8. Beneficiary’s last will and testament
9. Documentation of healthcare (primary and supplemental) and personal insurance plans
10. Documentation of government benefit plans
11. Professional retainer agreements (e.g., attorney, financial advisor, and tax advisor for estate and special needs planning)
12. Healthcare records (sorted by date and provider and organized with numbered pages or bates-labeled pages and a table of contents)
13. Court filings concerning the letter of intent beneficiary (e.g., petition for estate administration)

Storage Practices for a Letter of Intent

An LOI must be both readily accessible to those who need its information and protected against prying eyes. LOIs and their attached documents contain a wealth of data that could prove harmful if stolen by third parties. The LOI serves as a record of intimate personal details, addresses, financial information, and sensitive health information. Consequently, LOI writers and recipients

must take care to protect the privacy and security of both electronic and printed LOIs.

Like so many other digital documents, any LOI stored online or on a computer is vulnerable to online information piracy crimes, including identity theft, financial fraud, forgery, stalking, bullying, and cyber-hacking (e.g., National Cybersecurity Alliance 2020; see also U.S. Department of Homeland Security Cybersecurity and Infrastructure Security Agency 2020). There are numerous for-profit software companies and insurance plans who offer protected online databases for storing sensitive documents. Users of these services are encouraged to find an online platform that allows them to share access to LOI documents with others in a secure format. Additionally, an LOI author must be sure to record the access information (website, user name, log-in password) and share it with a backup contact (e.g., Arbaje 2020).

Another option for storing and distributing an LOI is to save it on a portable hard drive and to physically distribute the device to others. These drives should have password protection and data encryption to guard against hacking. Recipients of hard drive-based LOIs must understand that they should not download a drive's contents to their personal computers for data security reasons. Because of cybersecurity and privacy concerns, LOI users should avoid sending an LOI document via a regular email attachment or with a link to a general document storage site.

Lettick, Amy L. (1921–2017)

Linda Rumanoff Simonson
Benhaven, Inc., North Haven, CT, USA

Name and Degrees

New Haven Teachers College (NHTC), B.A., elementary education teaching certification

Yale University, Doctor of Humane Letters honorary degree

University of New Haven, Doctor of Humane Letters honorary degree

Major Appointments (Institution, Location, and Dates)

- Executive Director, Benhaven, Inc., 1967–1987
- Appointment to Connecticut Governor's Committee on Autistic Children, 1973

Major Honors and Awards

- 1973 – Asked by Dr. Bernard Rimland of National Society for Autistic Children

(NSAC) to tour with him to speak in nine different cities

- 1975 – Received Doctor of Humane Letters honorary degree from Yale University
- 1989 – Received Doctor of Humane Letters honorary degree from the University of New Haven
- Journals and other writings in Special Collection at Yale University's Sterling Memorial Library

Landmark Clinical, Scientific, and Professional Contributions

Amy Ladin Lettick was not a scientist, a researcher, or a clinician. Amy Lettick was a mother, a teacher, and a pioneer in the field of autism.

Amy Lettick was trained as a teacher in college and went on to teach for several years. Her training, experience, and drive served her well after giving birth to a son, Ben, later diagnosed with autism, at a time when there were few educational options available. When Ben turned 7, he aged out of The Yale Child Study Center's nursery school where he had been for 2 years. Amy took matters into her own hands, did her own research, and read two books by Dr. Newell Kephart of Purdue University (Kephart 1960; Strauss and Kephart 1955) which set her on a new path. After reading those books and successfully putting into practice Kephart's teaching procedures and techniques with Ben, Amy's mission became to find the financial backing and supports needed to start her own school where she could share her skills and knowledge with a new generation of teachers, students, and families. She accomplished this in 1967 when the first Benhaven School opened in New Haven, Connecticut, serving four children. Within 3 years, that number grew, necessitating the first of several moves. Over the next 50 years, what started with Amy's desperation and determination grew into a well-recognized and respected agency providing educational, vocational, and consulting services to hundreds of individuals and families.

Part of Amy's legacy was a commitment to lifelong learning. She championed adult

education even though public and most private schools stop providing services at age 21. To this end, volunteers from local high schools are trained to conduct lessons in communication, functional math, art, and even foreign languages to those residents who could not learn in community adult education settings. Many of these volunteers go on to become employees at Benhaven or to pursue an education and eventual career in autism or a related field. Those who can benefit from and tolerate community-based educational opportunities are supported in those settings.

Amy Lettick's vision of a school evolved in response to the needs of the individuals enrolled. Several years after it first opened its doors, Benhaven offered a pre-vocational program and, a few years after that, an employment program that included some workshop-based activities but actively sought community-based employment opportunities. Under Amy Lettick, Benhaven also purchased several acres of rural property on which greenhouses were erected, chicken coops stocked with egg layers, and vegetable gardens planted to provide more work and training options for the individuals it served.

Amy Lettick recognized the need not only for educational and vocational training for individuals with autism but experienced firsthand the lack of appropriate residential facilities, especially for those with disruptive and explosive behaviors. As a parent, Amy was well aware of the attention and energy required to care for a child with autism and the toll it could take on the family. Amy also strongly believed that residential care should not be custodial but be a place for active learning in a setting rich with natural opportunities to learn new skills. To this end, Amy Lettick opened the first of several residential homes in 1972, which served individuals from not only Benhaven's home state of Connecticut but also from Massachusetts, Rhode Island, New York, New Jersey, Texas, Ohio, Maryland, North and South Dakota, and as far away as Mexico during the residential program's first 12 years.

Amy Lettick was eager to collaborate with clinicians and researchers from Yale Child Study Center. That collaboration and cooperation began with Dr. Donald Cohen, Director of the Yale Child

Study Center from 1983 until his untimely death in 2001. It continued with Dr. Fred Volkmar, who replaced Dr. Cohen as Director of Yale Child Study Center, and that connection continues today. Many Benhaven students and residents have participated in a variety of studies over the years, contributing to the scientific and clinical knowledge that this research has provided. Fellows from there spend a year of their training as consulting psychiatrists for Benhaven, getting invaluable experience in reviewing case studies with Benhaven staff, and prescribing and monitoring a range of psychiatric medications and their effects on mood and behavior. Even Yale undergraduates have opportunities to learn from and interact with Benhaven students, residents and staff as they spend time at one of two schools or at one of the residences as part of a class requirement. Internship programs with other local universities and colleges have also been developed which continue to extend Benhaven's contribution to shaping future teachers and clinicians, and giving the community a better understanding of those with autism.

Amy Lettick started with a vision and a mission and turned it into a multifaceted learning, working and living environment that has yielded far reaching benefits for the individuals Benhaven serves, their families, the staff who are trained to support them, clinicians and researchers, college and university students, as well as the communities at large.

Short Biography

Amy Lettick's work with her son, Ben, and the subsequent establishment of Benhaven, had a significant and lasting impact on the field of autism, especially, but not limited, to the areas of education and residential treatment. As Amy's vision became a reality, her mission grew to include connections with other parents through individual relationships and through the National Society of Autistic Children, with Yale University, and in particular, The Yale Child Study Center, and with other institutions and individuals in the community. One of her main messages in those early

days was that these children, who at that time could not be served in traditional classrooms, would learn if taught within a structure of consistency and in ways that maximized their strengths. Although Amy Lettick proved herself to be a force of nature in promoting the education of those with autism, in her early days, she did not see herself in a teaching career.

Amy Lettick was born on August 27, 1921, in New Haven, Connecticut, the youngest of three children. Her parents emigrated from Russia, her mother at 2 years old and her father at age 17. Her father eventually owned a haberdashery store, and her mother worked in a factory until the birth of her children. Money was tight but her parents managed to send all three of the children to college. When Amy graduated from high school as an outstanding student and graduation speaker, she had earned scholarships, but not enough to cover transportation and living expenses at schools like Vassar or Wellesley. She knew that she would have to go to school locally, and so accepted a scholarship to New Haven State Teachers College. In her memoir, *Ways and Means* (Lettick 1998), she states that she never deliberately chose to become a teacher, but that was the only career open to her as a graduate of NHSTC. She said that she had never regretted it, especially in view of her needs years later.

Ben was the third of Amy's four children, and his tantrums, crying, destructiveness, and unpredictability required constant vigilance. She recognized that her family suffered from the need for constant surveillance of Ben, dealing with his odd and often bizarre behaviors and the stress of taking Ben on an outing. This awareness contributed to her desire, years later, to provide residential care in home-like settings as an alternative to the then current institutional facilities available.

Amy and Ben had the benefit of living near the Yale Child Study Center, and Ben was seen by Dr. Sally Provence and Dr. Ellis Perlschwig, a young psychiatrist. Amy brought Ben to the Center twice a week for an hour with the psychiatrist, while she met with a psychiatric social worker. During these years, Ben was enrolled at the Yale Child Study Center's nursery school; but when he was six,

Amy was told that he would be ineligible to attend when he turned seven and that they did not know of an appropriate place for him. Amy's story is familiar to any families who had children with autism in the 1960s, and sadly, many still struggle to find appropriate and adequate resources, especially after age 21.

In 1961, Amy struck up a correspondence with Rosalind Oppenheim, the mother of a child with autism who had written an article in a magazine that Amy had read. In it, she told of being rescued by Dr. Newell Kephart of Purdue University. Amy read two books by Kephart (Kephart 1960; Strauss and Kephart 1955) that Rosalind recommended and almost immediately took Ben by the hand, walked upstairs to a table in his room, and began his first class time. From that significant day in 1961 when Ben was 7 until 1967 when he was 12, she worked with Ben daily (Lettick 1998).

Amy kept detailed records of all those classes with Ben (Silverman 2011) and kept up a correspondence with Rosalind. They shared progress, despair, books and activities, and ultimately hope, as each of their boys made slow but observable improvements.

Amy discussed Ben's progress with Dr. Provence, and they agreed that taking Ben to see Dr. Kephart for an evaluation might give Amy some new methods of teaching Ben. Soon after, she and Ben travelled to Indiana and met with Dr. Kephart and his staff, and Amy said that she felt she was in the right place and getting the help she needed. Ben became a client of Kephart's Achievement Center for Children from 1962 until 1969, and Amy incorporated much of what she learned there into her teaching and training of teachers when she opened Benhaven School in 1967.

Since 1962, Amy had worked tirelessly pressing the New Haven school system to create a class for Ben and others like him. She finally succeeded in getting a class funded in 1966, but it never became a reality because a qualified person to run it was never found. When Ben turned 11 and there was still no place for him, Amy became convinced that unless she started a school, Ben would not get an appropriate education.

After investigating available services and finding nothing appropriate in Connecticut, Amy looked elsewhere. She visited the League School in Brooklyn directed by Dr. Carl Fenichel and the Nassau Center in Long Island directed by Dr. Joan Shodell. Both directors urged her to start a school and promised their help. By the end of that year, Amy started searching for board members, financing, and a location.

Amy shared her thoughts about her school (which her family had already named “Benhaven”), with Drs. Kephart, Fenichel, and Shodell, and their responses to her ideas helped shape her thinking. And although she was warned that parent-run schools had a very poor prognosis, she remained stalwart in her mission and opened Benhaven School on September 7, 1967, with Ben and two other boys as the first students.

Over the next 5 years, Benhaven outgrew that first school, as enrollment increased to 24 and then 34 students. During that period, Amy also began the search for funding and grants to open a residential home. This proved an arduous challenge with many frustrations and disappointments along the way. But in December 1972, just before Christmas, three Benhaven students, including Ben, moved into the first home. By 1974, the school was housed in a large four-story building; the residential home and swimming pool were situated on a 34 acre farm with a farmhouse and barns; Benhaven offered outpatient services, a professional training service, and parent training; and Yale Child Study Center was conducting research with Benhaven students.

Amy wanted to share her expertise and experience and inadvertently became an author. She made the first national presentation about Benhaven at the National Society for Autistic Children Conference in the summer of 1971. She was asked by the NSAC board to repeat the presentation five times so that more attendees could hear it. Amy decided then to turn her talk into a monograph to sell. Later she added lectures and teaching techniques and called the book *Benhaven Then and Now* (Lettick 1975). She turned down a publishing contract and chose to publish it through her own enterprise which she called The Benhaven Press; she sold several thousand copies.

She subsequently authored and sold more publications and tapes.

With all that Amy accomplished, one of her happiest and proudest moments was in December 1974, when she learned that she would receive an honorary degree from Yale University. On May 19, 1975, she received the honorary degree of Doctor of Humane Letters, an official recognition of her efforts and achievements. That was followed in 1989 by a Doctor of Humane Letters honorary degree from the University of New Haven.

Amy’s “can do” attitude and tireless efforts kept Benhaven growing even through many challenges including dismal financial crises. But by the time she retired in 1987, Benhaven had opened five more homes. Amy’s successor as Executive Director, Larry Wood, had worked at Benhaven for 17 years, starting out as a teaching aide, and so Amy was very comfortable turning over the mantle to him. Larry had proven himself as a visionary leader with the skills and determination to keep Benhaven growing and improving its services. Now, in 2019, Benhaven has 2 schools serving 67 students, 9 homes including 7 adult homes serving 36 residents with an eighth adult home in the planning stage, a Career and Transition Services program, 5 shared living homes, Individual Family Supports serving more than 60 families and 47 children and their families receiving support from Benhaven’s Children’s Behavioral Services program, and a consulting group. Those at the helm today demonstrate Dr. Lettick’s drive to find the best ways to serve more individuals and families while continuing to raise expectations for the level of professional development of its staff and the services provided.

In October 2018, Benhaven celebrated 50 years since its founding by Dr. Lettick with a gala affair. Almost a month to that day on November 22, Dr. Amy Lettick died peacefully in her sleep in Tempe, Arizona. She was 96 years old and lived a full and accomplished life.

Definition

Levetiracetam is an anticonvulsant; however, its mechanism of action remains unknown. While it has been suggested for use in many psychiatric disorders, including autism, evidence is conflicting and minimal. Side-effect profiles include headache, somnolence, dizziness, and asthenia. It is important to note that the mechanism of action is not similar to other anticonvulsants.

Liability

Jane Hamilton
 Quinnipiac University School of Law, Hamden,
 CT, USA

Definition

Liability

Liability is the type of accountability assumed by an individual or legal entity upon engaging in activity, which imposes on the individual or legal entity a specified standard of action and duty of care. The legal responsibility that is liability is enforceable by civil remedy and or criminal punishment (Garner 2004). The type of liability that attaches to an individual or entity depends on the nature of the action, as well as the nature of the relationship between the individual or to which entity the duty of care is owed to and the individual or entity being held liable.

Tort Liability

Tort liability is “the kind of legal responsibility that adheres to a person or legal entity as a result of an injury done to someone else or to some other entity” (Oller and Oller 2010). This type of liability applies in the event of an *injury*. Courts require a causal link between the injury suffered and an individual’s deviation from an accepted standard of care in order for the individual or entity to be held liable. However, there are circumstances under which a finding of fault is not required in order to hold an individual or entity liable for injury (see “[Strict Liability](#)”). The relationship between the parties plays a large role in the types of legal claims asserted in the event of an injury (see “[Malpractice Liability](#)”).

Malpractice Liability

Malpractice liability attaches to an individual or entity engaged in the practice of rendering services. For example, health care professionals are liable to their patients, and lawyers and legal professionals are liable to their clients. Malpractice liability is one of the most common legal claims made by client-plaintiffs against professionals. (Sales et al. 2005). In a malpractice suit, the client-plaintiff “alleges that he or she suffered a physical, mental, or financial injury because an [individual professional] did not exercise the level of ordinary and reasonable care practiced by the average member of that discipline in the same or similar community” (Sales et al. 2005).

Strict Liability

Strict liability is “liability that does not depend on actual negligence or intent to harm, but that is based on the breach of an absolute DUTY to make something safe” (Garner 2004). Therefore, strict liability will apply in appropriate situations to an individual or entity without requiring a showing that the liable party was at fault for the injury. “[S]trict liability most often applies either to ultrahazardous activities or in products-liability cases,” where individuals claim injuries (physical, mental, financial and otherwise) resulting from defective or otherwise dangerous products (Garner 2004).

Licensed Behavior Analyst

Michael F. Dorsey^{1,2}, Gordon Bourland³,
Grant Gautreaux⁴ and John W. Scibak⁵

⁵State Representative, Commonwealth of Massachusetts, South Hadley, MA, USA

A “Professional License” is based on the legal permission of a governmental agency to engage in a regulated activity. Regulated activities for professional licensure are generally a specified set of behaviors that define or belong to a profession, often articulated within the “scope of practice” of that profession found in the legislation developed to create such a license standard. The overarching purpose of licensure is to protect the public by requiring minimum standards to engage in a profession and by informing the public who has met those standards. Mandatory governmental regulations are designed to protect consumers

from inadequately trained and unethical practitioners and give consumers legal recourse should malpractice occur. For professions that require specialized education and training, licensure establishes legally enforceable standards that restrict practice to qualified individuals who have met specific qualifications in education and supervised work experience and have passed a formal examination process.

The requirements for licensure vary across states. Licensing laws generally include provisions to restrict the use of the professional title (e.g., “Applied Behavior Analyst”) to licensees or restrict non-licensed individuals from performing activities that are included within the licensing law’s scope of practice. Some state laws regulate both the title and the practice (e.g., Kentucky, Texas). A licensed behavior analyst is a person who has met the minimum requirements specified in the state’s licensure law and has been issued a license by the governing body, allowing them to engage in behavior analytic activities specified in the licensure law. The purpose of licensure is to protect consumers by restricting practice to individuals who have met specific qualifications as determined by the issuing entity. Licensing laws typically include civil or criminal penalties for the unlicensed use of regulated titles or engaging in the practice of the profession without a license. Licensure laws may also include specified ethical and professional standards and give governing boards the authority to suspend, place on probation, or revoke licenses if licensees have been found in violation of those standards.

Although licensure is common for many professions (e.g., medicine, nursing, K–12 education), licensure of behavior analysts is a fairly recent phenomenon, with Massachusetts, in 2008, being the first state to file a bill to license applied behavior analysts. Pennsylvania enacted the first law in 2008, followed by Nevada and Oklahoma in 2009. To date, 28 states have created statutory provisions for licensure of applied behavior analysts. At present almost all licenses for behavior analysts are issued by the states in the United States.

While the criteria for licensure of behavior analysts vary substantially, virtually all states

have articulated specific minimum requirements in education and supervised work experience as well as achieving a passing score on a formal examination. A number of states require that applicants meet the criteria for attaining certification as a Board Certified Behavior Analyst (BCBA[®]) as required by the Behavior Analysis Certification Board[®], while other states do not require this certification or have adopted more stringent standards. Some state statutes also regulate paraprofessional providers of behavior analysis services. Finally, the behavior analyst licensing statutes typically include exemptions for certain individuals (e.g., family members, academic faculty, and students) or for members of certain professions who might engage in behavior analytic activities within the scope of practice within their discipline (e.g., speech and language pathologists).

Because of the variability with respect to eligibility for licensure, states also differ in terms of reciprocity of licensure and ability to practice. Although some states do not currently license behavior analysts, they may have statutory regulations which prohibit individuals from utilizing the title “behavior analyst” without BCBA[®] certification (Connecticut). In addition, some third party payers may require licensure or certification for full reimbursement of services even if the state does not require practitioners to possess the credential.

In addition to identifying titles and activities that will be regulated, licensure laws also identify which entity will be responsible for overseeing the provisions of the law. The governing entity may be a board or a committee that operates independently or under the oversight of an existing board. Licensure laws also specify who will be a member of the board or committee. The governmental entity and members administering licensure of behavior analysts also vary across states. A few states have independent behavior analyst licensing boards (e.g., Louisiana, Kentucky), while other states have boards that regulate several different professions (e.g., Texas, Massachusetts), and others rely on a specially constituted committee that operates under the licensing board of another profession such as psychology (e.g., Missouri, Ohio).

A final component of licensure laws worth noting is exemptions; identifying certain individuals that are not required to be licensed. These exemptions vary from state to state but are generally centered on a few considerations. Since the licensure of behavior analysts is relatively new to the occupational regulation landscape, it is possible that other disciplines already include behavior analysis in their scope of practice. If this is the case, generally those professionals are exempted from being licensed as behavior analysts if they are already licensed as another type of professional. In addition, individuals who may practice behavior analysis with animals or organizations, academics who teach behavior analysis courses, and students of behavior analysis are also typically exempt from licensure laws.

Despite the variations in title and practice regulation, requirements for licensure of behavior analysts, governing entities, and exemptions across states, each of these efforts has been implemented to protect consumers of behavior analytic services. Restricting the practice of behavior analysis to qualified individuals, creating legally enforceable standards, ensuring behavior analytic practitioners meet minimum standards of competence and ethical behavior, and giving consumers the right to legal recourse are a few of the benefits of the licensure of behavior analysts.

Life Satisfaction in Autism

Kathleen B. Franke
The Unumb Center for Neurodevelopment,
Columbia, SC, USA

Definition

Life satisfaction refers to the subjective appraisal of one's satisfaction with their overall life circumstances. This concept may be conceptualized broadly, as individuals may vary in the relative weight of various life factors (e.g., family, friends, school, self) on their life satisfaction. Life satisfaction may also be domain-specific, such that

individuals may be asked to provide a rating of their satisfaction within specific areas. Further, life satisfaction may be distinguished from objective indicators of functioning, such as quality of life. The study of life satisfaction arose from the field of positive psychology, which emphasizes the scientific study of human flourishing; this emphasis on positive indicators of functioning is particularly important within the field of disability (see Schalock 2004 for a detailed discussion). Research with youth has demonstrated that focusing assessment on disordered symptomatology alone neglects important aspects of functioning, and optimal mental health assessment includes indicators of positive aspects of functioning (Greenspoon and Saklofske 2001; Suldo and Shaffer 2008).

Several life satisfaction measures have been validated for use with children and adolescents, including the Students' Life Satisfaction Scale, which is a brief measure that assesses youth's overall life satisfaction on a Likert scale (Huebner 1991). To obtain domain-specific ratings, the Brief Multidimensional Students' Life Satisfaction Scale may be used (BMSLSS; Huebner 1994). This measure assesses satisfaction in various domains (e.g., friends, family, neighborhood, school, self) on a Likert scale. Both measures require that individuals have the ability to comprehend short sentences and select a response on the Likert scale.

Research has recently begun to seek the perspective of children and adolescents with autism spectrum disorder (ASD) regarding life satisfaction. McDougall et al. (2012) surveyed 400 children and adolescents with chronic conditions, 35 of whom were diagnosed with ASD. Participants completed global and domain-specific measures of life satisfaction, and the results indicated that youth with chronic conditions reported high levels of life satisfaction. On the BMSLSS, participants' mean score corresponded with the response options indicating that youth were "mostly satisfied" or "pleased" with their lives. Further, youth responses were highly correlated with parental estimates of their children's life

satisfaction; this level of agreement was consistent with that obtained in studies assessing caregiver-youth agreement within typically developing populations (Dew and Huebner 1994; Gilman and Huebner 1997). In a study primarily assessing quality of life, Egilson et al. (2017) administered the psychological well-being scale of the KIDSCREEN-27 with 96 youth with ASD. This subscale asks participants to rate their satisfaction with and enjoyment of their lives. When compared to peers without ASD, those with ASD reported lower levels of satisfaction. Consistent with previous research, Franke et al. (2019) administered the BMSLSS with 46 adolescents with ASD and their caregivers, and the results indicated that youth reported high levels of life satisfaction across domains. However, they reported significantly lower levels of family, friend, self, and overall life satisfaction than did a typically developing comparison group. Within this study, youth's self-reported levels of life satisfaction correlated with self-reports of self-efficacy, self-awareness, persistence, school support, family coherence, peer support, emotion regulation, empathy, optimism, and gratitude. While there is limited research directly assessing life satisfaction in individuals with ASD, the implications of the current body of work suggest that youth with ASD view their life as satisfying. However, this level of life satisfaction may be slightly below that of youth without ASD.

Limbic System

Cyndi Schumann

UC Davis M.I.N.D. Institute, Sacramento, CA, USA

Definition

The term “limbic system” generally refers to a group of brain structures located on the inner border of the cerebrum. They are thought to play a role in processing emotions (Fig. 1).

Historical Background

The list of brain structures considered to be part of the “limbic system” has evolved significantly since its initial conception (Papez 1937; Maclean 1949). Most often the list includes the amygdala, hippocampus, cingulate cortex, septal nuclei, thalamus, and hypothalamus as core structures. The term “limbic” is considered somewhat obsolete by most neuroscientists since there are no accepted anatomical or functional criteria for which structures should be included as part of the system (LeDoux 2000). However, the term is still used to describe the general group of structures that contribute to emotional function in the brain.

Limbic System, Fig. 1 Brain structures commonly associated with the limbic system

General Function of Limbic System Structures

Amygdala

The amygdala is an almond-shaped brain region made up of a group of nuclei located in the anterior portion of the temporal lobe (Freese and Amaral 2009). A widely held view is that the amygdala is essential for learning the emotional significance of a stimulus in the environment, detecting potential danger, and adjusting levels of vigilance. The amygdala plays a modulatory role in social behavior including recognizing emotion in faces, judging the trustworthiness of a person, and generating a sense of personal space (Adolphs 2010).

Hippocampus

The hippocampus is located in the medial temporal lobe posterior to the amygdala. The primary functions of the hippocampus are to consolidate short-term memories into long-term memories and perform spatial navigation (see “The Hippocampus Book”, ed. Andersen, Morris, Amaral, Bliss, and O’Keefe). The hippocampus was originally the centerpiece for the limbic system concept (Maclean 1949); however, studies of patients with hippocampal lesions, sustained by seizures, Alzheimer’s disease, or surgical removal, demonstrate a distinct deficit in the ability to form and retain new memories while still able to regulate emotional states.

Cingulate Cortex

The cingulate cortex is a gyrus that wraps around the top of the corpus callosum on the medial surface of the brain and is typically divided into two regions, the anterior cingulate and the posterior cingulate. The anterior cingulate plays a role in several cognitive functions such as decision making, empathy, reward anticipation, motivation, and error detection as well as autonomic functions such as blood pressure and heart rate. The posterior cingulate is part of a “resting state” network that is active when a person is introspective or “daydreaming” in which thoughts are directed to the past or future as well as the interaction between

emotions and memory (Maddock 1999) and the detection of familiar voices and faces.

Thalamus

The thalamus is a bulb-shaped mass consisting of a group of subnuclei. The thalamic nuclei are located on the medial surface of the brain under the corpus callosum and above the brainstem and hypothalamus. The primary function of the thalamus is to relay sensory information between cortical and subcortical areas, in that it receives sensory signals (i.e., visual, auditory, somatosensory) and sends them to the appropriate brain regions for processing (Jones 2007). The thalamus also plays an important role in regulating sleep and arousal.

Hypothalamus

The hypothalamus is located below the thalamus and contains a group of subnuclei that regulate the secretion of hormones and metabolic processes, such as body temperature, blood pressure, appetite, thirst, fatigue, sexual and maternal behavior, and circadian rhythm.

Septal Nuclei

The septal nuclei, located below the most anterior portion of the corpus callosum, plays a primary role in experiencing pleasure, analyzing reward, and reinforcing behavior based on the value of the reward.

Current Knowledge

Pathology and Dysfunction of the Limbic System in Autism

Impairments in emotional processing are one of the central features of autism. This suggests the possibility that the structures within the limbic system would be pathological in people with the disorder (Amaral et al. 2008; Courchesne 2004). The amygdala, perhaps more than any other structure in the brain, has been found to be both structurally and functionally abnormal in autism. There is some evidence for hippocampal pathology in autism, but the main function of the hippocampus

in memory does not appear to be affected in autism. There is little evidence that shows abnormalities in the structure of the cingulate gyrus in autism. However, many imaging studies have shown the function of the cingulate to be affected.

There is little evidence for pathology in the thalamus, hypothalamus, and septal nuclei in autism. These regions, however, serve an important role in controlling the physiology and function of many other brain regions. For this reason, they may indirectly lead to the pathology of autism. Since there is clear evidence showing the pathology within the amygdala, hippocampus, and anterior cingulate cortex in autism, these regions of the brain will be discussed further below.

Amygdala

An emerging hypothesis suggests that the amygdala plays a role in directing visual attention to people or things in the environment that pose a potential threat or are critical to survival. In humans, the amygdala particularly directs visual attention to the eye region of the face to allow for detection of important social and emotional cues. However, several studies have now shown that people with autism spend less time looking at the eye region of the face. A study done by Dalton and his colleagues (2005) shows that the amount of time people with autism spend looking at the eye region of the face is strongly and positively correlated with amygdala activation. This means that when people with autism do look at the eye region of the face, the amygdala is activated, but they do this less often and therefore the amygdala is activated less often. However, this is a chicken and egg question. Do people with autism spend less time looking at the eye region of the face because the amygdala does not direct attention there, indicating that they do not go seeking emotional and social cues the same way as typical developing individuals do? This possible explanation suggests that normal function of the amygdala is to direct attention, based on motivation, to attend to the eye region of the face. Thus, individuals with autism are simply less motivated to look at people in the eyes (Pierce et al. 2004). Or, a second possibility is that they purposely do not

look at the eye region of the face because they perceive social interaction and eye contact as threatening and which therefore increases their level of anxiety. Given the amygdala's role in fear and anxiety, one can predict heightened amygdala activation in people with autism when they engage in eye contact, as found in the Dalton et al. (2005) study. This might be caused by increased emotional, or even fearful, response when autistic individuals look at another person's eyes.

The amygdala is also structurally pathological in autism. However, the nature of the pathology changes with age. For example, studies of younger children show that the amygdala is enlarged in those with autism compared to typical children (see Schumann et al. 2009 for review). However, studies of older adolescents, adults, or a wide age range of subjects have found either no difference or even smaller amygdala volumes in individuals with autism. In addition, the amygdala continues to grow in size throughout adolescence in typically developing male children, but this growth pattern does not seem to take place in male children with autism (Schumann et al. 2004). Recent evidence from studies of children early in development suggests considerable heterogeneity in amygdala growth among those with autism. Nordahl et al. (2012) found that within subgroups, some, but not all, children with autism have a rapidly growing amygdala. It is unknown if children in different subgroups also have a different form or cause of autism.

Therefore, on average, the amygdala appears to be initially larger than normal in children with autism. It, however, does not go through the same preadolescent increase in volume that takes place in typically developing children. There is some evidence that a decreased number of neurons may lead to the reduction in amygdala volume later in adulthood (Schumann and Amaral 2006). It is unclear if the reduction in neuron number is present early in development, and some other factor contributes to the early increase in volume, or if there is a degenerative process taking place in the amygdala in people with autism.

Hippocampus

There is some evidence that the anatomical development of the hippocampus in individuals with autism is different from that of a typical development. In general, studies have found either no difference or a moderate enlargement (Schumann et al. 2004) in hippocampal volume between autism and typically developing control subjects. Shape analyses and proton magnetic resonance spectroscopy ($^1\text{H-MRS}$) that are used to characterize concentrations of brain metabolites have been used as an indication of pathology (see Dager et al. 2008 for review).

Margaret Bauman and Tom Kemper carried out the first groundbreaking studies during the mid-1980s to early 1990s to systematically describe pathology in a sample of postmortem brains from people with autism (Bauman and Kemper 1994). Over this series of studies, they collected and described six cases of autism. Five of these cases had mental retardation and four had epilepsy. They did a side-by-side comparison of each autism case with an age- and sex-matched control. They then observed that neurons in the amygdala and hippocampus of most autism cases appeared unusually small and more densely packed (i.e., increased numbers of small neurons per unit volume) than in age-matched controls. These findings suggest abnormalities at an early stage in brain development, a time at which the size of neurons is not fully mature. These changes could result in a curtailment of normal brain maturation.

Recent studies also propose widespread abnormalities in the GABAergic system of the brain in individuals with autism, including the hippocampus (Blatt et al. 2001; Guptill et al. 2007). GABA is the chief inhibitory neurotransmitter in the brain that regulates the communication between neurons. It is unclear if or how an abnormally functioning GABAergic system in the hippocampus might result in behavioral impairments in autism. Another possibility is that an abnormally functioning hippocampus might actually result in improved spatial or declarative memory in people with autism (see Schumann et al. 2004 for review).

Hippocampal pathology in autism may not directly result in obvious behavioral impairments; but it may be linked with the occurrence of seizure disorder. Approximately 30% of individuals with autism also have some form of epilepsy with a strong correlation between intellectual impairment and seizure prevalence (see Tuchman et al. 2010 for review). Abnormalities in the GABAergic system in the hippocampus could reduce the threshold for development of seizures in children with autism.

Cingulate Cortex

Structural MRI studies have not indicated either the anterior or the posterior cingulate as areas of obvious pathology in autism. In a longitudinal MRI study, Schumann et al. (2010) reported that the cingulate cortex, along with the frontal and temporal cortices, grew at an abnormal rate in young children with autism. By 2.5 years of age, these regions were enlarged relative to typical children at the same age. In contrast, there is significant evidence from functional imaging studies that suggest abnormal activation and connectivity in these regions (see Minshew and Keller 2010 for review).

In the seminal postmortem studies carried out by Kemper and Bauman (1993), anterior cingulate cortex was the only region of neocortex that shows abnormalities. The cortex is typically organized into layers of neurons; the layers in the autism cases were not as organized as this typical control cases. There are also abnormalities in the GABAergic system in the anterior cingulate that may affect normal neuron communication (Oblak et al. 2009).

A recent study found abnormalities in the white matter below the anterior cingulate, which is made up of fiber tracts (i.e., axons) for neurons to communicate over various distances in the brain. Specifically, they found an excessive number of thin axons, which link neighboring areas together, and a decreased number of large axons that communicate over long distances (Zikopoulos and Barbas 2010). This study suggests that the connections in the brain did not develop normally in autism, which may affect communication between brain regions and

subsequently lead to behavioral abnormalities. However, this study only examined four brains from people with autism and therefore more studies are needed.

There is little evidence that suggests the posterior cingulate to be pathological in individuals with autism. Oblak et al. (2011) have reported that there are changes in the distribution of neurons. This suggests that there is a defect during prenatal brain development in which neurons do not migrate to the correct location in the cortex. This study also found abnormalities in the GABAergic system as well.

There is some evidence that the anterior cingulate is not functioning properly in autism. One study found that the anterior cingulate is activated more in adults with autism relative to typical adults while performing a task that required sustained attention for a monetary reward (Schmitz et al. 2008). The more socially impaired the person is, the more activated the anterior cingulate becomes during this task. The anterior cingulate is thought to be involved in cognitive aspects of error detection and risk assessment during reward tasks. This increased activation in autistic adults can either be caused by their need to compensate for other impairments or that the monetary reward is a greater incentive.

Individuals with high functioning autism also do not activate the cingulate cortex as much as typical individuals do while looking at familiar faces; this suggests that they have a lower emotional response to people they know personally (Pierce and Redcay 2008). People with autism also do not show normal activation in the “default network” during rest; this lack of activation indicates a lack of introspective and self-reflective thinking (Kennedy and Courchesne 2008).

Linguistic Idiosyncrasies and Neologisms

Patricia Prelock

Communication Sciences and Disorders, Dean's Office, College of Nursing and Health Sciences, Burlington, VT, USA

Definition

Autistic language often contains unique features and characteristics including linguistic idiosyncrasies and neologisms. Linguistic idiosyncrasies can be defined as the atypical use of a standard word or phrase to express a specific meaning. While the word used is part of the speaker's native language, it is not typically associated with the word or phrase of reference. Neologisms can be described as words that have been created by a speaker and are not considered to be part of the lexicon of a given language. Although, words have been created or coined using old words to create new words. For example, the word “webinar” was originated from “seminar” but one that occurs on the web or the internet. Many children with autism use neologisms or made-up words to refer to specific objects, people, or situations within their environment. For example, a child with autism might call a black and blue mark or bruise, a “blusier.”

As newly coined lexical units, neologisms do create problems for understanding. In fact, in the technical world of computers, translators are often needed to make sense of these new literary units

(Moghadam and Sedighi 2012). Interestingly, there are several ways to create neologisms (see Delabastita 2004, as cited in Moghadam and Sedighi 2012, p.1) including:

- *Borrowing*: integral borrowings (e.g., hobby [English →Dutch, French, etc.]), loans showing graphological or phonological adaptation (e.g., hobby [German]), and structural loans (also known as calques, e.g., sky-scraper).
- *Shifting*: existing words undergo semantic shifts (e.g., bug [concealed microphone]) or grammatical shifts (e.g., foreground, sideline [noun →verb]).
- *Combining*: new formations through derivation (e.g., Thatcherite) and/or compounding (e.g., bubble-headed), or else new collocations (e.g., lateral thinking).
- *Coining*: words are created out of the blue (e.g., Joyce's quark).
- *Imitating*: words are formed by onomatopoeic imitation of noises or sounds (e.g., zoom).
- *Blending*: words are formed from the parts of two others (e.g., channel + tunnel →chunnel).
- *Shortening*: clippings (e.g., science-fiction →sci-fi) acronyms (e.g., AIDS).

Neologisms and idiosyncratic use of language is often seen in psychiatry in individuals with schizophrenia or thought disorders. In these cases, the language is typically difficult to understand or make sense of the context. For children with autism, it appears they often have a unique way of expressing their wants, needs, and observations, particularly as they frequently cannot find the "typical words" to express themselves. Some examples of idiosyncratic language use might be helpful in understanding a child's approach to create meaning with the words to which he or she has access. For example, families have reported the following:

- Instead of asking for a cracker, a child with ASD might say "I want a snack, NOT from the refrigerator and NOT wet. Crunchy from the big cupboard."
- A 6 year old with ASD said "Mommy, can we go again on big snowy mountain rollercoaster

with scary monkey?" instead of asking the name of the roller coaster and then saying "Can we go on Expedition Everest again?"

- A child with ASD might describe things instead of using the correct name. For example, "Fritos are crunch crackers in orange bag that fold to make a letter C."
- A child with ASD responded in the following way when his brother hit him on the arm: "Mommy, Ryan make my skeleton hurt" while holding his arm and crying rather than say "Mommy, Ryan hurt my arm."
- An 8 year old with ASD said "Fix Florida" when he pointed to a scab on his knee in the shape of the state of Florida.
- A 7 year old with ASD asked his mom: "See Dr. Mike" when he had a headache and did not feel well.

Often for children with ASD, with familiarity and context knowledge, family members and care providers can determine the meaning being created by the idiosyncratic use of language or the creation of neologisms. Research in this area of autism is limited but provides an opportunity to examine what approaches (e.g., coining, blending, imitating, etc.) children are typically using to create new words and what profiles of linguistic and cognitive functioning are typical for children with significant idiosyncratic language use.

Listening Comprehension

Aparna Nadig
School of Communication Sciences and
Disorders, McGill University, Montreal, QC,
Canada

Synonyms

[Comprehension](#); [Receptive language](#); [Spoken language comprehension](#)

Definition

Listening comprehension encompasses the multiple processes involved in understanding and making sense of spoken language. These include recognizing speech sounds, understanding the meaning of individual words, and/or understanding the syntax of sentences in which they are presented. Listening comprehension can also involve the prosody with which utterances are spoken (which can, e.g., change intended meaning from a statement to a question), and making

relevant inferences based on context, real-world knowledge, and speaker-specific attributes (e.g., to what information the speaker has access and about what he/she is likely to be talking). For longer stretches of language or discourse, listening comprehension also involves significant memory demands to keep track of causal relationships expressed within the discourse. It is often viewed as an active process with three main components: attending to the perceptual input (speech), constructing meaning from stretches of speech, and relating what was heard to existing knowledge.

In typical development and developmental disorders other than autism spectrum disorder (ASD), comprehension precedes or is stronger than production, especially early in development. In individuals with ASD, delays in and difficulty with comprehension are common, and the gap between comprehension and production is reduced, though children with ASD still comprehend more words than they produce.

The understanding of written language, or reading comprehension, is assessed separately.

Literacy

Maura Moyle and Claire Plowgian
Speech Pathology and Audiology, Marquette
University, Milwaukee, WI, USA

Synonyms

[Reading](#); [Writing](#)

Definition

Literacy refers to the ability to read and write and to use these skills functionally in social, academic, and vocational contexts. Individuals with proficient literacy skills are able to comprehend text and effectively express ideas through written language. While the decoding skills of individuals with ASD are often within normal limits, they frequently exhibit poor reading comprehension, particularly with narratives and other complex texts. In addition, they may have difficulty with written expression. The ability to read and write effectively can be an important asset for individuals with ASD. Strategies such as providing scripts for activities of daily living (e.g., asking for help at the grocery store) and encouraging the use of written communication (e.g., e-mails) can help enhance their communicative functioning.

Lithium

Jeffrey Glennon
Department of Cognitive Neuroscience, Radboud
University Nijmegen Medical Centre, Nijmegen,
The Netherlands

Synonyms

[Lithium carbonate](#); [Lithium citrate](#)

Indications

Mania, depression, aggression, mood disturbances.

Mechanisms of Action

Lithium is an alkali metal and is among the oldest employed psychoactive therapeutic agents. Despite this, its precise mechanism of action remains unclear. These have been as varied as reported modulatory effects on neurotrophic factors, biogenic amines/enzymes, adrenergic function, postsynaptic receptor and supersensitivity,

and second messenger systems including adenylate cyclase, inositol triphosphate, and protein kinase signaling cascades (Alessi et al. 1994). There is, however, a consensus that much of lithium's action is via replacement of sodium ion functionality within the body, particularly in its indirect inhibition of neuronal processes. Inhibition of both adenylate cyclase and protein kinase C has been implicated in anti-manic effects associated with lithium. In terms of its action on biogenic amines, lithium is associated with a stimulatory effect on dopaminergic, noradrenergic, and serotonergic transmission. Recent studies have suggested actions on neurotrophic and neuroprotective mechanisms by changing the ratio of neurotrophic (Bcl-2 and BDNF) to apoptotic (BAX and p-53) factors and inhibition of GSK-3B and of *N*-methyl-d-aspartate receptor-mediated Ca^{2+} influx.

Lithium is also associated with an increase in the white blood cell and platelet count, an effect mediated by its stimulation of granulocyte-macrophage colony-stimulating factor as well as increasing *N*-acetyl-aspartate, a marker of neuronal integrity and gray matter volume. Taken together, it has been suggested that lithium may have protective actions which affect corticolimbic circuitry thought to be involved in affective, behavioral, and emotional regulation. As such, it has been proposed that its action on this circuitry may be involved in its utility in autism.

Specific Compounds and Properties

Lithium is available in a number of salt forms, of which the two most routinely prescribed are lithium carbonate and lithium citrate. Lithium carbonate is generally available in 400 mg tablet formulations, each of which contains 10.8 mmol lithium. Lithium citrate is available in both liquid and tablet formulations (564 mg tablets). Each of the 564 mg tablets contains 6 mmol lithium. The liquid formulation of lithium citrate is available in two strengths (5.4 mmol/5 mL (equivalent to approx. 200 mg of lithium carbonate) and 10.8 mmol/5 mL (equivalent to approximately 500 mg of lithium carbonate)) for twice daily

administration. While the pharmacokinetics of the two most commonly prescribed formulations of lithium are similar, there are important differences in their bioequivalence. It is extremely important that the patient receives the same formulation each time upon a new prescription as confusion in this area could result in suboptimal or even toxic dosing.

The absorption of lithium from the GI tract after oral administration is usually good with maximal blood serum levels usually being achieved in 1–4 h. In terms of its metabolism, this is relatively minor with the primary substance being left unchanged such that 95% of the oral lithium taken is excreted by the renal system. This usually results in typical half-lives of approximately 24 h. Impairment of the kidneys or renal disease will usually impair lithium excretion with the result that the half-life is increased, requiring careful monitoring and reduction of the dosage prescribed. Since lithium acts to replace sodium ion functionality, any change to serum sodium levels can have a major impact on lithium concentrations and their clinical effect. The absorption and excretion of lithium is closely regulated by changes in sodium. For example, excessive sweating, dehydration, or diarrhea will lead to sodium depletion and, as a consequence, plasma lithium levels will be elevated. Equally, dietary changes in salt consumption should be monitored as these can also influence effective lithium serum concentrations.

Clinical Use (Including Side Effects)

Lithium is most commonly utilized as a mood stabilizing agent, particularly in the treatment of manic depression. In the context of autism, it is often used as an antiaggressive agent and for its mood stabilization properties. Other mood stabilizers are also in clinical use in autism such as carbamazepine, which is also employed in the treatment of comorbid seizures. Lithium has key prophylactic actions against both manic and depressive symptoms but is more successful in the management of acute mania compared to acute depression. While initial studies in the

1960s and 1970s demonstrated high clinical response rates in clinical trials, the clinical practice of lithium use has been inhibited by the increasing recognition that its effectiveness as a mood stabilizer in clinical practice is mixed coupled to an increased awareness of its side effect profile. In terms of its use in autism, it is occasionally utilized against aggression and irritability with mixed success.

The utility of lithium as an effective medication in autism is debatable. While some case reports have demonstrated efficacy against aggression measures; full-scale clinical trials have shown mixed results with lithium use. In spite of this, one study in prepubertal children with severe aggression in conduct disorder showed positive effects (Campbell et al. 1995) and its use in autism is typically as an anti-aggressive agent. Furthermore, it has been suggested that the combination of lithium with other pharmacotherapy may offer improvement versus lithium alone. For example, positive results have been reported for the combination of lithium and fluvoxamine against mood disturbances and aggression. One disadvantage of using lithium is that the therapeutic effect is gradual, often taking 1–3 weeks to achieve efficacy and is dependent on patient compliance (since drug administration is orally). Coupled to this, other agents (such as antipsychotics) can be administered in other ways (e.g., intramuscularly) to noncompliant patients and are often associated with more rapid effects on aggression inducing rapid sedation.

In spite of these mixed studies of lithium's efficacy against aggression, it remains a strong candidate where mood disturbances are indicated, but the narrow range of dosing available for titration with lithium in children, adolescents, and adults with autism is of concern. Toxic side effects, notably nephrotoxicity and cardiotoxicity in chronic lithium users, are serious adverse risk events mitigating against the widespread clinical utility of lithium in autism. As a result of such serious adverse events, medication with lithium should be carefully controlled with frequent blood tests necessary for the evaluation of its safety. In other clinical populations, lithium may be of use in treating comorbid aggression (Lettinga et al.

2011), but its treatment in autistic populations may be better performed by atypical antipsychotic agents such as risperidone.

Prior to commencement with lithium therapy, laboratory screening should be performed to assess renal and thyroid function in addition to a complete blood count and ECG. The excretion of lithium is via the kidneys, thus impairment of renal function could alter plasma drug concentrations and dosing required. In terms of thyroid function, lithium is associated with a decrease in free tri-iodothyronine and thyroxine which are normally compensated for in euthyroid patients by elevating thyroid-releasing hormone levels. Patients with impaired thyroid function lose this compensatory mechanism. While lithium does not often induce cardiac complications, it does increase cardiac conductance and is associated with elevated white blood cell and platelet counts. Furthermore, lithium is often associated with cardiac repolarization (ST segment and T-wave) and in one fifth of patients with T-wave flattening. All of these changes should be carefully monitored at half-yearly intervals while lithium is prescribed. In the case of family-planning issues, lithium is often associated with birth defects in pregnant women, and thus its use during pregnancy should be avoided with contraception advised to women of child-bearing age who are taking lithium.

Therapeutic blood concentrations are reported to lie between 0.5 and 1.2 mmol/L with associated side effects being more marked at higher concentrations. Ideally, lithium levels should be measured every 12 h since the last administered dose concurrent with clinical observation.

Therapeutic blood serum levels of lithium are often between 0.5 and 1.2 mEq/L (0.5–1.2 mmol/L) with associated side effects being more marked at higher concentrations. Administration is generally well tolerated, taking 1–2 weeks to achieve a clinical response. Initial doses are usually between 300 and 600 mg orally with elevation by the same amounts in 4–5-day intervals to therapeutic doses of 900–1500 mg daily divided across two doses. In children under 12 years of age, doses are typically 10–30 mg/kg per day resulting in a daily 900 mg dose in a 30 kg child divided across two to three doses. A 450 mg

sustained-release capsule is also available. Dosing resulting in serum levels over 1.5 mEq/L is often toxic. It is advisable to take medication orally after food in order to minimize gastrointestinal (GI) side effects. Ideally, lithium levels should be measured every 12 h since the last administered dose concurrent with clinical observation.

Typically, side effects are moderate but more serious issues can also arise. Children, adolescents, and adults generally tolerate lithium intake well with side effects typically including a dry mouth, metallic taste, nausea, vomiting, diarrhea, headache, tremor, and weight gain. In terms of more serious side effects, ataxia, dysarthria, polyuria, polydipsia, tremor, weakness, and mild, short-term cognitive impairment and confusion can occur. Polydipsia in particular is a side-effect feature seen in twice daily lithium dosing. Lithium-induced tremors tend to be irregular in rhythm and amplitude, often affecting the fingers. These movements of the finger flexion and extension often have a jerky character. The adrenergic beta-blockers such as propranolol, metoprolol, and nadolol can be useful therapeutics in the management of lithium-induced tremors. Some skin conditions such as acne or psoriasis can be exacerbated by lithium usage. Lithium has a low therapeutic index and so regular blood serum monitoring is warranted. Some side effects (notably polyuria) tend to become more frequent when blood serum lithium levels are above 1 mmol/L. In patients taking lithium chronically, monitoring for potential hypothyroidism should be considered which can be remediated by thyroxine replacement therapy. Hypothyroidism as a side effect of lithium is quite common with middle-aged women particular suffering from this side effect (up to 20% of users in this age group). Thyroid function usually returns to normal after discontinuation of lithium use. Lithium treatment can also increase the risk of hyperparathyroidism and as such, chronic lithium use should be accompanied by blood serum calcium level monitoring.

Long-term lithium use can also be associated with nephrotoxicity and cardiotoxicity. Approximately one-fifth of patients demonstrate a decrease in the glomerular filtration rate which is often benign but can result in a very small subset

of patients in interstitial nephritis. Similarly, lithium can also induce nephrogenic diabetes insipidus (hence the occurrence of polyuria and increased thirst) but this is usually reversible except in extreme long-term (>15 years) users.

Above serum lithium levels of 1.5 mmol/L, mild gastrointestinal, cardiac, and CNS toxic effects of lithium are apparent, with disorientation, seizures, coma, and death occurring at serum concentrations above 2 mmol/L of lithium. If suspected, lithium use should be discontinued and blood samples sent for analysis of serum lithium, creatinine, and electrolyte concentrations in order to guide the rate and nature of fluid replacement. Treatment of lithium toxicity should employ osmotic diuresis or forced alkaline diuresis with toxic serum lithium concentrations above 3 mmol/L requiring peritoneal or hemodialysis. An ECG should also be performed if lithium toxicity is apparent as there is a risk of cardiac arrhythmia. Dependent on the individual, there can be quite a wide variation in the degree and severity of toxic side effects coupled to different serum lithium levels and as such it should be managed on a case-by-case basis.

Litigation, Parent-Initiated

John W. Thomas
Independent Educational Consultant, Durham,
NC, USA
Quinnipiac University School of Law, Hamden,
CT, USA

Parent-initiated lawsuits alleging that school districts have failed to provide appropriate services for their children with ASD are governed by the Individuals with Disabilities Education Act (IDEA). IDEA establishes a parent right to sue, specifies the applicable procedural steps, and allows for parents to bring suit on their own without the assistance of an attorney.

The Right of Parents to Initiate Litigation

Section 1415(i)(2)(A) of IDEA provides that “any party aggrieved by the findings and decision” of a

school district “shall have the right to bring a civil action.” An aggrieved party may file a civil lawsuit in either state or federal court.

In its 2007 decision in *Winkelman v. Parma City School District*, the United States Supreme Court recognized that parents who object to a school district’s educational plan under IDEA are “parties aggrieved.” Thus, the parents may file suit against school districts.

In *Winkelman v. Parma City School District*, the United States Supreme Court also implicitly recognized three grounds for parental lawsuits under IDEA. Parents may challenge the substantive sufficiency of the Free Appropriate Public Education (FAPE) that the school district provides, may challenge the adequacy of the procedure accorded the parents, and the parents may sue for private school expenditures necessary to provide a child with an appropriate education.

The Procedural Steps

The regulations that accompany IDEA provide that each state must establish a State Educational Agency (SEA) to address complaints filed by parents and other aggrieved parties. In addition, the SEA must promulgate written procedures for resolving complaints.

Unless state law specifies otherwise, aggrieved parties must file complaints with the SEA “within two years of the date the parent or agency knew or should have known about the alleged action that forms the basis of . . . complaint.” The complaint “must remain confidential.”

The school district must respond to the parent’s complaint within 10 days of receiving it. The response must include “[a]n explanation of why the agency proposed or refused to take the action raised in the . . . complaint,” describe the procedures it used to reach its decision, and articulate other options that it considered and rejected.

Within 15 days of receiving notice of the complaint, the district must convene a meeting with the parent and members of the Individualized Education Program (IEP) Team that took the action about which the parent has complained. If

the district fails to resolve the complaint to the parent's satisfaction within 30 days, the SEA may hold a due process hearing to assess the complaint's validity. If the parent fails to participate in the hearing, the SEA hearing officer may dismiss the complaint.

Unless state law specifies otherwise, parents have 90 days following the hearing officer's decision in the due process hearing to file a civil lawsuit.

The IDEA regulations also provide that states allow the parents and school district to resolve disputes through a mediation process. Participation in mediation is voluntary and the utilization of mediation alters the dispute resolution timeline by allowing time for the parties to reach a resolution through mediation.

Finally, the regulations that accompany IDEA provide that states must develop and make available model complaint forms. The state may not, however, require that parents or other aggrieved parties use the model forms.

Right to Proceed Without an Attorney

In *Winkelman v. Parma City School District*, the United States Supreme Court held that parents can prosecute an IDEA civil suit pro se, without utilizing the services of an attorney.

Definition

Adult residential models offer individuals with autism a range of services that support different levels of independence, input, and community integration. This article reviews independent living, supported living, group home, and ICF-MR models of residence and the variations and issues surrounding these programs.

Historical Background

The history of adult residential programs follows the progression from overcrowded large-scale institutions that function on a custodial care model to a continuum of services designed to support independence and foster community integration for all individuals on the autism spectrum. The deinstitutionalization movement emerged as the world became more aware and accepting of individuals with disabilities, causing a social shift toward inclusion and better treatment. The growth in social consciousness was matched by the

government passing legislation that increased patients' rights, subsidized the creation of new programs, and reduced the financial burden on individuals, allowing them greater choice in treatment.

At the turn of the century, the social and political approach to individuals with disabilities was segregation. There were two options for individuals with disabilities: live with their family with no services or move into a government institution (Gerhardt 2009). Since their creation in the late nineteenth century, institutions were overcrowded. By 1940, a third of American institutions had between 2,000 and 5,000 residents each (the maximum holding 9,177) (Braddock and Parish 2001). The patients had few rights and no public voice. As the overcrowding problem increased, the courts gave more control to the institutions, resulting in increased sterilization, lobotomy, shock treatment, and euthanasia. Institutions functioned on a custodial care model, providing the most basic necessities for life but offering little treatment and no freedom.

Beginning in the 1950s, the parents of disabled children began to organize and advocate for the development of services and programs that could keep their children out of institutions. Private schools and day programs were developed focusing on the needs of children diagnosed with intellectual disabilities, many of which would not accept children with an autism diagnosis (Gerhardt 2009). Autism at this time was still struggling for recognition. It was frequently misdiagnosed as childhood schizophrenia, intellectual disabilities, or various psychiatric disorders. Programs designed for children with ID did not meet many of the social and communication needs of children with autism (Van Bourgondien and Elgar 1990).

With the election of John F. Kennedy, mental health and the country's treatment of disabilities was brought to the forefront of national consciousness. The President's Panel on Mental Retardation produced 95 recommendations to reduce the need for institutions through community services and greater integration into society. It also required all 50 states to develop plans to create preventative services and improved

residential options. JFK transitioned the national attitude away from segregation toward giving citizens with mental illness a place in American society (Braddock and Parish 2001). The 1963 Mental Retardation Facilities and Community Health Centers Construction Act sparked the creation of both public and private nonprofit community health centers.

President Kennedy commenced the migration out of institutions into smaller community-based homes. In the 1969 President's Committee on Mental Retardation, Dr. Bengt Nirje described this as the normalization movement. The driving principle of the movement was to give the mentally disabled a life that is as close to the norm as possible (Mesibov 1976). This was implemented by creating community-based programs and developing new models of residential services that focused on the humanization of the residents.

The early 1970s brought a series of landmark developments in public policy and law that enhanced the lives of individuals with intellectual disabilities and drove society further away from institutions. *Wyatt vs. Stickney* gave the right to treatment to all individuals experiencing mental illness (Mesibov 1976). Institutions could no longer simply maintain a custodial care mentality; they were required to provide treatment to all of their residents. During this time, Medicaid was founded as part of the Social Securities Act, which gave federal monies to facilities that met ICF/MR standards. This meant that states would be refunded 50–78% of the costs of institutions if they could meet a series of requirements, including providing a certain amount of space per resident, causing a steady decline in the number of residents per institution. In 1967, there were 194,000 people in institutions; by 1998, it had been reduced to 52,801 (Braddock and Parish 2001). The guidelines required institutions to become more homelike, but they still maintained a medical model with residents required to utilize in-house doctors and treatment plans (Sullivan 2007).

The further erosion of institutions came in 1981 with the Omnibus Budget Reconciliation Act. Wolf Wolfensberger had shifted the focus of the normalization movement from the individual

to the organizations that shaped their lives (Mesibov 1976). He made it clear that a typical life could never be achieved in an institution and home-oriented alternatives needed to be created. This act empowered Medicaid to reimburse home and community-based services, including case management and new models of residential programs (Laudicina and Burwell 1988). This opened the door to group homes, independent living, and supervised living programs, as well as day programs and vocational support. Programs were now able to offer a range of services, addressing the needs of all individuals on the autism spectrum.

Current Knowledge

In 1982, a survey of 93 adults with autism found that 16% lived in residential programs; that number rose to 53% by 1991 (Howlin 2000). This trend reveals a rising demand for residential services that shows no signs of slowing down. The developmental disabilities community has responded to this need by creating a continuum of residential models designed to address the varied needs of all individuals on the autism spectrum. These programs range from optional services designed to provide unobtrusive support allowing individuals to live a typical life to residences with 24-h staff and a team of professionals implementing individualized treatment plans to address severe behaviors and medical problems. Each model recognizes autistic individuals' desire to be a part of the community, have control of their environment, and maintain the full extent of independence that they are able to achieve. From the programs that require the highest independence level to the lowest, this chapter will review independent living, supported living, group homes, and ICF-MR facilities.

Independent Living

Even high-functioning adults can have trouble living independently. In a literature review by Howlin and Goode, they found that out of 66 adults, only 11 lived without any supportive services (Volkmar 2005), and the British

National Autistic Society noted that only 3% live without any professional support. Independent living programs are designed to provide their clients with the support to live independently in their own residence. They believe that all people can benefit from support no matter what their level of functioning. The average client is independent enough to lead a typical life but invests in services to improve their lifestyle and provide support when necessary. To be in the program, they must be able to determine their own needs and goals. All of the services provided are directed by the consumer and designed to fit individual needs.

Many programs begin by helping their clients find a residence that fits their economic restrictions and select appropriate roommates if desired. Once in their own home, they are offered classes in self-care, creating a nutritional diet, home care, budgeting, and how to navigate social and work environments. They offer different levels of involvement in their clients' lives, from visiting offices and meeting with family to private instruction. A primary goal of these programs is to build a community network of those in similar situations. They have community events to encourage social interaction and involvement.

Income, independence, and social ability are major obstacles preventing individuals from enrolling in this type of program (Leblanc et al. 2008). Acquiring and holding a high-paying job in order to afford your own residence and support services is especially difficult for adults with ASD. They must have basic household and self-care skills to maintain a residence and a healthy lifestyle. The services encourage them to take certain classes, but the client needs the self-awareness to choose the curricula that is most beneficial to them. The client also requires a certain level of social interaction in order to obtain a house or an apartment, enroll in services, and be part of a neighborhood.

The British National Autistic Society utilizes the independent living program model in several areas throughout the United Kingdom. They provide individualized levels of service, ranging from 1 h a week to daily meetings. At the high-functioning end of their service, they help

individuals develop nutritious diets and budgets their income. A major goal is to take part in community events and social activities, such as horseback riding, bowling, or attending the cinema.

The independent living model is emulated in colleges around the country. Students with autism attending school meet with advisers twice a week to discuss roommate relations, academic strategies, time management, home and self-care, and the social aspects of college life. These programs focus on the unique challenges autistic students face in the academic and social aspects of university life.

The Achieving in Higher Education with Autism/Developmental Disabilities (AHEADD) program was developed by Carnegie Mellon and now offers its services to schools across the USA. The program is designed to facilitate independent living along with academic support for college students. Its services help their clients develop advocacy skills for their own academic success by educating them on how to manage classes, professors, and workload. They are taught how to live independently, navigate campus, and utilize all of the services available to them as a student with a disability. Along with academic support, they are paired with a peer who meets with them socially once a week and mentors them on the social aspects of college life. They also provide a series of social events, such as picnics, parties, athletic groups, and bowling, to create a community within the program.

Supported Living

Many adults with ASD prefer to live at home or in their own residence but require increased involvement and supervision from professionals. Supported living is designed to allow individuals who are not a danger to themselves and are able to make responsible health and life choices but do not have the ability to navigate life without significant support. These programs allow individuals the freedom to choose where they want to live and have input into their daily schedules. They target autistic adults who face communication, social, or sensory/motor challenges and are not ready for the vast amount of choices required in

an independent living program but would be too limited in a group home setting.

Clients of supported living programs are visited each day by direct-care workers, who provide them with individualized support. This can range from providing daily schedules and vocational support to aid and instruction in self- and home care. Programs include 24-h crisis care and overnight support when needed. The benefit of this level of residential program is that it provides individuals with the support to avoid inpatient care. They are now able to determine where they live and work and have the freedom to engage in the community whenever they would like.

An excellent example of supported living is the California-based Jay Nolan Community Services. Jay Nolan was originally established in 1975 as a series of group homes serving the autistic community in Los Angeles. In 1992, they found the group home model to be too limiting and decided to shift their focus toward greater community integration. They dissolved their group homes and built a supported living program to replace them. They believe that individuals with developmental disabilities can maintain a full life within the community if they are provided with the right support and assistance.

Their organization provides two main services that are matched together: personalized day support/supported employment and supported living. The personalized day program views involvement with an organization, whether through employment or volunteering, as a critical part of integrating with the community and crucial to reaching independence. Clients are individually matched with an organization that they are involved with each day. If their disability makes a full day of work too difficult, the rest of their day is filled with meaningful community-oriented activities. The supported living program provides assistance and support to fulfill their residential needs. Each client builds a "circle of support" that includes representatives from Jay Nolan, family, friends, health-care professionals, and the client themselves. The circle of support determines which services the individual will receive and the direction of their curriculum and their goals for the coming year.

Group Homes

Group homes exist for individuals that require 24-h direct-care supervision because of physical disabilities or behavior problems that cannot be adequately handled by the family. Each group home is owned and run by an organization that makes all of the staffing selections and residential decisions. The staff provide constant care, supervision, and guidance with everyday decisions. Most have a nurse on staff, immediate response crisis care, and staff trained to handle emergency situations and behavior problems.

Since the deinstitutionalization movement, group homes have been striving to separate themselves from the asylum image that they evoke in many people. The new model for group homes is to be as much like a family home as possible. They reach for a homelike aesthetic with lighting, house design, furniture, and personalized bedrooms. The residents participate in maintaining the household to the best of their ability through chores and cooking. The number of residents per house has fallen from an average of 20 to between 2 and 10 individuals, and many are residences built for families rather than for institutions (Sullivan 2007).

Group homes have moved on from the “custodial care” model of the past to focus more on the resident’s participation in the home, community integration, and self-determination. The organization that runs the group home still decides daily activities, when to visit the community, and the curriculum goals for each individual, but they have built in a system for input from the resident and their families. The curriculum is designed to develop self-care skills and social activities within the household. There are scheduled community outings, and residents are matched with daily work programs.

The major criticism of group homes is that residents and their family have little input into decisions (Gerhardt 2009). The amount of say each resident has in curriculum and programming depends on the group home they are in and the level of their disability. Residents do not have input into large decisions, such as staffing, housemate selection, or house and grounds expansion and construction. The

company that owns the home must balance its resident’s needs with their own financial goals and the needs of the greater disabled community.

Group homes also suffer from exceptionally high staff turnover. There is an average 50% yearly resignation rate with an average of 10–11% of positions left open per home (Gerhardt and Lainer 2010). Working in a group home is both physically and emotionally taxing, requiring the staff to build positive relationships with the residents, handle severe behavior problems, and understand the underlying disability with little financial recompense or training. Direct-care staff are not required to have a degree, special training, or any experience in the field. Staff with degrees quickly move on to higher-paying jobs. Due to the turnover, most homes do not have their target number of staff, which increases the client-to-staff ratio and the workload of each staff. In most cases, new staff are needed to immediately fill the turnover gap resulting in only basic training, leaving a gap in their understanding of the disability (Van Bourgondien and Schopler 1990). Despite their responsibilities, direct-care workers are given low pay, inadequate benefits, and little professional status leading to no direct career path.

Aside from increasing staff stress and workload, the turnover rate can take a toll on the residents themselves. The social and communication deficits experienced by individuals with autism combined with intense desire for sameness and routine can make it difficult to integrate new people into their lives. Each new staff member will teach curriculum in divergent ways or utilize different communication techniques, especially if they have only been briefly trained, which can cause loss of a resident’s cognitive and social gains. A stable workforce creates continuity in the clients’ care and has been shown to increase the resident’s social interactions (Van Bourgondien and Schopler 1990). To combat loss of employees, organizations employ different strategies ranging from creating opportunities for advancement within the organization to having their staff live in the group home itself in a room separate from the residents.

The family teaching model of group homes is designed to maximize staff stability for its residents. A married or committed couple lives rent-free while providing direct-care services to two to four young adults with autism (Gerhardt 2009). They are encouraged to make the residence as much their home as possible and build a family-like rapport with the residents. The Princeton Child Development Institute's Family Focus homes have found success in this model, designing their curricula to include family-style activities and using the family unit as a stepping stone to interact with the community.

ICF-MR Facilities

ICF-MR facilities are designed to address the needs of individuals who have both autism and intellectual disabilities. The majority of residents also have major health problems or comorbid diagnoses, ranging from seizures, mental illness, visual or hearing loss, ambulatory disabilities, or behavior problems (Gerhardt 2009). These facilities follow the same design as a group home with 4–10 individuals per residence and curricula focused on self-care, communication, and social development but are better equipped for severe behavior and health problems. They feature an on-site nurse, advanced staff training in behavior and health problems, and 24-h emergency critical care. They typically maintain a larger number of staff, reducing the client-to-staff ratio and turnover.

The focus on resident's health care and mental illness needs places ICF-MR homes in the same category as hospitals, institutions, and treatment centers (Wall 1990). This status gives them access to federal Medicaid monies, which reduces the cost to individuals and their family and gives them a wider field of treatment options. They are subject to the same restrictions and regulations as medical facilities, requiring them to meet many of the same documentation, bureaucratic, and policy standards as hospitals and large institutions. It is a major challenge to meet these standards while maintaining a homelike, comfortable, family atmosphere.

The residents of ICF-MR facilities require a variety of medical professionals to meet their

needs. The facility maintains a close relationship with the physicians and mental health care professionals in the area but gives their residents the freedom to decide who they go to for care. A key to successful treatment is that the facility builds a consensus within a resident's medical team and constructs a coordinated and consistent plan. The facility then meets with the resident or their guardian and builds their needs and goals into the plan.

If an ICF-MR facility cannot meet the medical or behavioral needs of a resident, they must enter an intensive inpatient behavior care unit. These are short-term residences, not exceeding 6 months, which provide their clients intensive therapy to deal with extreme aggressive behaviors targeted at both themselves and others (Gerhardt 2009). The individuals entering these programs have experienced an increase in behaviors that would result in needing to find a more restrictive living situation or in a medical state where they need to detox off medication that is managing severe behaviors. The professionals utilize behavioral interventions, cognitive therapies, skill trainings, and a process of medication assessment and trials to teach the patient to regulate their own behaviors and maintain their own mental health.

One of the most successful intensive inpatient behavior care units is the Kennedy Krieger Institute's Neurobehavioral Unit. They have provided care to patients from across America and from many countries around the world. Their therapy is derived from applied behavior analysis and focus on assessments of behavior, the effects of reinforcement, and parent-child interaction. A key component to their program is training the care givers and people who work with the individual in unified techniques and strategies to handle behaviors and maintain their client's stability. This process begins months before the client is released, ensuring that they enter a supportive and therapeutic environment that will maintain the gains they made within the institute.

A concern of both group homes and ICF-MR facilities is finding a place for their residents in the workforce. Employment is the foundation of persons placed in the community and provides important opportunities for social interaction and building communication. Kessissoglou and

Farrell showed supported employees gained independence, self-esteem, and became more responsible through employment (Mawhood and Howlin 1999). Many programs provide their clients with a separate day program in a sheltered workshop or supported employment in the community. Farmstead programs merge residential and vocational programs by providing work opportunities on campus.

Farmsteads are group homes or ICF-MR facilities that are built on land that is designed to maintain agriculture and raise farm animals. The residents maintain the grounds, raise animals, grow the crops, and sell what they make alongside direct-care workers who are trained in farm work. This type of work is immediately meaningful, has a visible effect on the surrounding environment, and encompasses a large spectrum of abilities. Tasks that range from harvesting crops and building retention walls to separating seeds and feeding animals provide work that meets the physical and mental needs of each resident. This model gives work opportunities to individuals with severe disabilities or extreme behavior problems who may not be able to work safely in the community.

Division TEACCH's Carolina Living and Learning Center (CLLC) is an ICF-MR facility that resides on 79 acres of land, has 15 residents in two houses, and provides supported employment to 2 individuals from group homes in the area. The center is an exemplary example of the effects of the TEACCH method. Individualized structure has been built into every aspect of resident's life from work systems to social interaction. Residents transitioning into the CLLC show marked increases in communication, social skills, independence, and a reduction of behavior problems (Van Bourgondien et al. 2003).

The vocational program revolves around both residents and the direct-care workers maintaining several large vegetable gardens. By taking part in every step in the life cycle of vegetables, from planting to cultivating, and finally eating what they have grown, residents take pride in their part of the process. They also engage in a variety of nonagricultural work such as making soap and potpourri to cooking pesto

and salsa. Periodically during the year, the residents sell what they have made at local events. Each day after work or on weekends, they go on community outings, either to attend local events, go shopping, or for exercise. Integrated into both the vocational program and their evenings is a curriculum of communication, self-care, and household skills that are designed specifically for each individual.

The continuum of residential models focuses on the needs of the current autistic community. Adults with autism have a wide variety of options that support their independence, foster their growth, and build a place for them in the world. As the population ages, a new complication looms on the horizon: retirement. The level of medical care and the type of activities and outings in the current models are not designed to meet the needs of the elderly, and the typical retirement community does not have staff trained to aid autistic individuals. Residential Services Inc. is the first organization to address this problem head on. They have built a facility that is designed to meet the needs of elderly individuals at all levels of the autism spectrum.

Residential Services Inc. is a North Carolina-based organization who developed their autism program with support from the TEACCH program. They provide the developmentally disabled community with all levels of services from residential programs to independent living support. They maintain 16 residences that are divided into group homes, ICF-MR facilities, and homes that are rented to autistic individuals as part of a supported living arrangement. Their Community Vocational and Learning Services program provides supported employment to residents in need of a job and their Life Options program is an enhanced day program for individuals requiring ICF-MR level of care.

The Spring Glen Retirement Community combines their experience with all levels of the autism spectrum into care for the elderly. The facility is made up of 15 units that are designed to match each model on the residential continuum. Each unit is designed to meet the varied needs of individuals and maximize their independence. Some units are built for highly

independent individuals and include a kitchenette and in some cases are part of a larger two-bedroom suite. Other units are designed to meet the standards of an ICF-MR facility and offer increased supervision, medical care, and support. They share communal activity rooms, spaces for therapy, dining rooms, gardens, walking trails, and a pond. The communal areas are often used for large group activities to foster friendships and build an air of community.

As the number of individuals with autism seeking residential care rises, residential services continue to grow and adapt services to the needs of the autistic community. Adults with autism can choose a model that will maximize their independence, build a place in the community, and find the best path to personal growth.

Future Directions

The United States Census Bureau estimates that there will be over 1,495,264 adults with autism in America by 2016. The majority of these individuals will require some form of residential services. In 1998, the wait list for residential placement in the USA had reached 87,000 and has only risen since (Gerhardt and Lainer 2010). The current system is not prepared to meet the needs of the autistic population today, much less the growing numbers of individuals aging out of student services. In the coming years, residential services will need to not only expand the number of individuals it serves but also the types of services it provides.

For the first time in United States history, autism is high on the national agenda. The rise in the population of individuals with autism has been recognized by the news media which has caused a wave of awareness in society. President Obama has not only made autism a priority but designated his first appointee with autism to the National Council on Disability. This prompted talk of new legislation that will create and fund new residential programs across the country.

With the growing population, the options available to adults with autism must expand to meet new and different needs. If we continue

only down the route of community integration and standardizing residential models, it may lead us to an ineffectual system (Schopler and Hennike 1990). There is already a trend in residential services toward innovation and experimentation, as seen in the family teaching model, farmstead programs, clustered apartments, and many others. The flexibility of the models will include both services offering community integration and others that would not. Some modern ICF-MR facilities follow the institution model to meet the needs of individuals with severe disabilities. The Murdoch Developmental Center houses 550 individuals with autism of all ages, who suffer from extreme behavioral challenges. In the coming years, we will see an expansion of residential programs to house the rising population and meet their changing needs.

Definition

The Local Education Authority (agency) is the public entity that is responsible financially and for planning the educational program for an individual receiving special education services. The LEA is also responsible for monitoring and reporting data to state and federal agencies. Frequently, the LEA is the district in which the individual receiving services lives, but there can be other instances in which a public entity could be determined to be the LEA.

Locus Ceruleus

Susan Y. Bookheimer
Department of Psychiatry and Biobehavioral Sciences, UCLA School of Medicine, Los Angeles, CA, USA

Definition

The locus ceruleus is a small brain structure located in a part of the brainstem called the Pons. This structure is the site in which an important excitatory neurotransmitter, norepinephrine, is manufactured and sent to other parts of the brain. Norepinephrine plays a role in many brain functions including homeostasis, stress, fear, mood, and sleep. The connections of the locus ceruleus are vast but include part of the amygdala, cingulate cortex, hypothalamus, medial frontal cortex, cerebellum, and spinal cord. The locus ceruleus is not directly implicated in autism and there is no evidence of pathology in the structure (Martchek et al. 2006), though there have been speculations of such a link (Mehler and Purpura 2009).

Lofexidine

Zachary J. Williams^{1,2} and James C. McPartland³

¹Medical Scientist Training Program, Vanderbilt University School of Medicine, Nashville, TN, USA

²Yale Child Study Center, New Haven, CT, USA

³School of Medicine, Child Study Center, Yale University, New Haven, CT, USA

Definition

Lofexidine is a medication of the alpha-2 agonist class with a molecular weight of 259.13 g/mol and a chemical formula of C₁₁H₁₂Cl₂N₂O. It is a structural analog of the alpha-2 agonist clonidine (see ► [“Clonidine”](#)). It was originally approved in Germany to treat hypertension but was withdrawn due to a lack of clinical efficacy (Gish et al. 2010). Lofexidine can be used as a short-acting antihypertensive, but it is primarily used to assist with opioid detoxification. It is approved in the UK for this purpose under the trade name BritLofex. While extended-release formulations of the alpha-2 agonists clonidine and guanfacine (see ► [“Guanfacine”](#)) are approved by the US Food and Drug Administration (FDA) to treat attention deficit-hyperactivity disorder (ADHD), lofexidine has not been studied for this purpose (see ► [“Attention Deficit/Hyperactivity Disorder”](#)). The FDA has not currently approved lofexidine for clinical use in the United States.

Like other alpha-2 agonists, lofexidine works by binding to alpha-2 type adrenoceptors in the central nervous system (see ► [“Noradrenergic System”](#)). This action, specifically in the locus coeruleus, helps to counteract the autonomic symptoms of opioid withdrawal. These alpha-2 receptors respond to high levels of catecholamines (i.e., epinephrine and norepinephrine) in the blood and exert negative feedback on descending sympathetic nerves that project to the adrenal medulla and stimulate catecholamine production. By activating the alpha-2 receptors, lofexidine simulates higher blood catecholamine levels, thereby lessening sympathetic input to the

adrenal medulla and reducing catecholamine production. Catecholamine levels in the blood subsequently drop, reducing both heart rate and blood pressure. Furthermore, increased activation of alpha-2 adrenoceptors in the prefrontal cortex is thought to mediate the effects of alpha-2 agonist medications on ADHD symptoms.

Lofexidine shows a high affinity for the alpha-2A adrenoceptor subtype, which is thought to be responsible for its reduced antihypertensive action relative to clonidine. Hypotension may still occur in some subjects, particularly those who are elderly or taking additional antihypertensive medications. In addition, transient increases in blood pressure have been noted following abrupt discontinuation of lofexidine.

Adverse effects of lofexidine are similar to other alpha-2 agonists and include sedation, insomnia, dry mucous membranes, dizziness, weakness, and hypotension. When compared with clonidine, lofexidine is reported to have a lower incidence of adverse effects, particularly hypotension and sedation.

One small trial has assessed the effect of lofexidine in children with autism, focusing on its reduction of concomitant ADHD symptoms. Using a double-blind placebo-controlled cross-over design, Niederhofer et al. (2002) administered lofexidine to a group of children with autistic disorder who also presented with significant symptoms of distractibility, hyperactivity, and impulsivity. The study reported reductions in both parent and teacher symptom ratings, primarily in the domain of hyperactivity. However, clinician-rated symptoms did not differ between lofexidine and placebo. No sedation was reported in the trial, but several children experienced hypotension, requiring reduced dosing of lofexidine. Although no further studies have replicated lofexidine's effects on ADHD symptoms in autism, a larger placebo-controlled trial of extended-release guanfacine also reported significant reductions in hyperactivity scores (Scahill et al. 2015). While further research is needed to explore the clinical utility of alpha-2 agonists in autism, it is unclear whether lofexidine offers any benefits over similar agents already approved by the FDA.

Outcome; Prospective

Definition

Longitudinal studies in autism are important for several reasons: First, they help to inform families and clinicians about the range of outcomes that may be expected in relation to a diagnosis such as autism. Additional reasons include opportunities to monitor change in symptom profile and comorbidities such as medical problems, as well as the ability to follow the acquisition of activities of daily living such as friendship, vocational skills and self-help. If predictor or mediator variables are identified that are potentially modifiable these may inform the development of new intervention strategies that could be tested in randomized control trials.

Longitudinal studies comprise a set of study designs that have the following features in common. The designs are (1) observational, i.e., they involve studying individuals that have been naturally selected to a particular group or exposure as compared to random assignment by researchers to a particular group as in experimental designs; (2) the individuals are sampled by exposure (or diagnosis), not by outcome as in case-control studies; and (3) they are generally prospective, i.e., the individuals of interest are followed chronologically and reassessed at one or more later time points. Such studies are very useful for a number of reasons but commonly used to examine predictors and outcomes. Predictors are early factors or characteristics of the individual or his/her environment that are associated with variation in later-occurring outcomes. Outcomes may be consequences of a diagnosis or of early predictors of interest. Longitudinal studies can also be used to investigate developmental trajectories or the rate of change in a domain over time. Mediators and moderators of outcome can also be studied as a special class of predictor variables. Mediators are variables that might account for change over time, and moderators are variables that modify the association between predictor and outcome.

Prospective cohort studies assemble a group of similar individuals (a “cohort”) at one time point. These individuals are then followed up over one or more time points to determine whether and how variation in certain baseline factors relates to

variation in outcomes of interest. If the cohort is followed over three or more time points (including baseline), trajectories or pathways of particular symptoms, abilities, or characteristics may be plotted to describe the rate and shape of change over time. Such designs also minimize measurement error due to recall bias. Drawbacks of these studies include greater expense and length of time to complete data collection.

Lorazepam

Emma Lecarie
Yale Child Study Center, New Haven, CT, USA

Synonyms

[Ativan](#); [Benzodiazepine](#)

Definition

A benzodiazepine medication used to relieve anxiety. Lorazepam is also used to treat irritable bowel syndrome, epilepsy, insomnia, nausea/vomiting from cancer treatment, and to control agitation caused by alcohol withdrawal. Additionally, it is used for surgery to interfere with memory formation and to sedate those who are being mechanically ventilated. Lorazepam works by slowing activity in the brain to allow for relaxation. It acts as a sedative, hypnotic, anticonvulsant, and has muscle relaxant properties. Lorazepam primarily works by modifying the amount and action of gamma-aminobutyric acid (GABA), specifically enhancing the effects of the GABA neurotransmitter at the GABA receptors by increasing the frequency of opening of the chloride ion channels of the GABA receptors.

Lorazepam was developed by D.J. Richards, the President of Research of Wyeth Pharmaceuticals, in 1977. This benzodiazepine comes as a tablet or concentrate to take by mouth and is usually taken two or three times a day with or without food. It can also be given as an injection into a muscle or vein, with the onset of effects occurring between one and thirty minutes and lasting for up to a day. If lorazepam is taken intravenously, the individual should be closely monitored. Lorazepam also comes in the forms of a skin patch, an oral solution, and a sublingual tablet. Lorazepam is high-potency and fast-acting, with a biological half-life of only 10–20 hours. The brain has extra benzodiazepine drug receptor capacity, so larger doses of lorazepam leads to stronger and longer-lasting effects. Since it is fast-acting, lorazepam works best to treat fast onset panic anxiety.

Common side effects of lorazepam include sedation, weakness, sleepiness, unsteadiness, dizziness, confusion, low blood pressure, decreased effort to breathe, increased risk of suicide for those who are depressed, and inhibition of the formation of new memories. Physical and/or psychological dependence may occur. Larger doses of lorazepam may be required to acquire the same effect if being used long-term. Benzodiazepine withdrawal syndrome may occur if lorazepam is stopped suddenly after long-term use. Withdrawal symptoms occur in one-third of individuals who have been using benzodiazepines for

longer than 4 weeks. Relatedly, it may be necessary to increase doses to sustain effectiveness if lorazepam treatment continues for longer than 4–6 months. Lorazepam is used to treat elderly individuals with either anxiety or other related conditions. Long-term cognitive effects, including reduced recall and psychomotor slowing, in addition to the absence of therapeutic benefit, emphasizes the cognitive toxicity of long-term use of lorazepam in this population.

GABA receptors have been found to be reduced in the parietal cortex, frontal cortex, and cerebellum, which are three brain areas that have been associated with the development of autism. This finding suggests widespread GABA dysfunction in the brains of individuals with autism and the relation to the use of lorazepam to enhance the effects of the GABA neurotransmitters. The safety of lorazepam in children with autism has not been proven. There are no currently approved medications to treat the core symptoms of autism. Benzodiazepines are being used to treat the epilepsy and anxiety symptoms in children with autism. Lorazepam has been found to moderately improve catatonic symptoms, or the inability to move normally, in multiple cases of individuals with autism. It is considered a safe and effective medical treatment for catatonia in ASD. Lorazepam has also been studied as a potential medication for aggression in autism. It was not found to have a significant effect on aggression and may have an inhibiting effect on the outcome of decreased aggression due to exercise.

Name and Degrees

Dr. Catherine Lord

Ph.D. in Psychology and Social Relations, Harvard University

Major Appointments (Institution, Location, Dates)

Dr. Lord is currently Director of the Center for Autism and the Developing Brain (CADB) at Weill Cornell Medical College and an attending psychologist at New York Presbyterian Hospital. She also currently holds the following appointments:

Professor of Psychology in Psychiatry, Psychiatry, Weill Cornell Medical College 2012-present.

Professor of Psychology in Pediatrics, Pediatrics, Weill Cornell Medical College 2012-present

Previous positions include:

Visiting professor, NYU Child Study Center and NYU School of Medicine Previously, 2008–2009

Uri Bronfenbrenner Distinguished Professor of Psychology, Psychiatry and Pediatrics, University of Michigan, Director of the University of Michigan Autism and Communication Disorders Center, 2001–2010

Professor of Psychiatry, University of Chicago, 1993–2001

Clinical Professor of Psychiatry, University of North Carolina, Chapel Hill, 1990–1993

Assistant Professor, Associate Professor and then Professor of Pediatrics, University of Alberta School of Medicine, 1982–1990

Assistant Professor at the Institute of Child Development, University of Minnesota, 1977–1981

Major Honors and Awards

Dr. Lord has received over 35 awards and honors from local, national and international bodies, too many to identify individually here, but a few noteworthy honors and awards include:

National Science Foundation Graduate Fellow, 1971–1975

National Institute of Mental Health (NIMH) Research Scientist Award, 1995–2000

Fellow, Society of Clinical Psychology, American Psychological Association, 1998

Chair, Committee on the Effectiveness of Early Intervention in Autism, National Academy of Science/National Research Council 1998–2001

Fellow, Society for Child and Adolescent Clinical Psychology, 2002

Irving B. Harris Early Childhood Award, 2004

Fellow, Association for Psychological Science, 2010

American Psychological Association (APA) Award for Distinguished Contribution to Applied Research, 2010

Award for Distinguished Scientific Contributions to Clinical Psychology, Society of Clinical Psychology, 2011

American Psychological Association (APA) Society of Clinical Child and Adolescent Psychology Lifetime Achievement Award, 2013

Member, National Academy of Medicine, 2014

Landmark Clinical, Scientific, and Professional Contributions

Catherine Lord has contributed significantly to the field of autism research in many domains, including her seminal longitudinal studies on early diagnosis of the disorder (Anderson et al. 2014; Lord et al. 2006), her contributions to understanding the nosology and basic characterization of core deficits of ASD, and her involvement in developing and testing treatments (Lord and Jones 2013; Lord et al. 2005). While these contributions have formed the basis for much of our understanding of the behavioral features of ASD, arguably, her most significant contribution lies in her work on the development and validation of standardized diagnostic instruments for individuals with ASD of different ages and abilities. Through her training and collaborations with Sir Michael Rutter, she created the Autism Diagnostic Interview (Le Couteur et al. 1989), and then the Autism Diagnostic Observation Schedule (Lord et al. 1989), two of the most widely used and well-established instruments for diagnosis and phenotypic characterization in clinical and research settings across the world. Dr. Lord collaborated in the development of the Social Communication Questionnaire (Berument et al. 1999), which is a widely used screening tool. More recently, Dr. Lord has been involved in several other measure development efforts, largely inspired by calls from the ASD research community that different types of measures are needed for different purposes. These include the Autism Screening Interview (ASI), a brief telephone interview of ASD symptoms (Bishop et al. 2016), the Brief Observation of Social Communication Change (BOSCC; Grzadzinski et al. 2016), a measure designed to capture change in social-

communication symptoms in response to treatment, and the Observation of Spontaneous Expressive Language (OSEL), a measure of spontaneous, functional language in children with ASD (Kim et al. 2014).

In addition to her numerous scientific contributions, Dr. Lord has had a major impact on clinical practice and policy in the field of ASD by contributing to various local, national and international efforts. Locally, one of the many examples is her contributions to the development of both research and treatment for TEACCH, a state-wide program in North Carolina that has served as a model for educating children with autism throughout the world. Nationally, Dr. Lord was chosen to lead or serve on many committees charged with developing and publishing guidelines for the field. One highly significant example was her role as chair of the committee on educational interventions for children with autism sponsored by the National Academy of Sciences, which resulted in the landmark publication (Lord and McGee 2001). From 2007 to 2014, she served on the DSM-5 committee that provided updated diagnostic guidelines for ASD and other neurodevelopmental disorders. She has continued to lead the field by providing up to date summaries of research and recommendations about how to implement current best practices for diagnosis and treatment of ASD within the community (Lord and Bishop 2010; Lord and Bishop 2015).

In the last 10 years, Dr. Lord has been part of larger efforts to extend ASD research beyond behavioral characterization of ASD and promote interdisciplinary cooperation between clinical and neurobiological researchers. She has helped lead several highly influential efforts designed to elucidate biological markers and genetic aspects of the disorder. For instance, she was part of a core group of scientists involved in developing the Simons Simplex Collection (SSC), a publicly available repository of cell lines and phenotypic data from probands with ASD and their family members (Fischbach and Lord 2010). Her leadership in behavioral phenotyping for this project has helped facilitate numerous genetic discoveries (e.g., Sanders et al. 2015) and has also allowed for multisite evaluation of diagnostic practices for

the disorder (Lord et al. 2012). Through these efforts, Dr. Lord has repeatedly emphasized the importance of considering the developmental aspects of the disorder, using findings to illustrate that developmental trajectories of behavioral variables may be most important in advancing understanding of the biology of ASD (Lord et al. 2015).

Short Biography

Dr. Lord is a clinical psychologist who has worked as a clinician-researcher in Canada and the USA and has collaborated and contributed to autism research worldwide. In her various positions, she has split her time between evaluating children, adolescents, and adults with ASD and engaging in major research efforts to lead the field in diagnosis and characterization of ASD across the lifespan. Dr. Lord has also advised numerous graduate students, post-doctoral fellows, and early-career researchers, many of whom now hold clinical and/or research positions at institutions in the USA and abroad. She began her career in autism as an undergraduate, where she was a student at UCLA at the time when Dr. Ivar Lovaas was working on his groundbreaking treatment paradigm for children with developmental disabilities, applied behavioral analysis. Having worked directly with children with autism under his supervision, it was at this point that she developed a passion for helping children with autism learn to talk. After graduate school in psychology at Harvard University, she interned at TEACCH, a one-of-a-kind program in North Carolina that includes services throughout the lifespan for individuals with autism, where she later returned to launch one of the longest lasting longitudinal studies of autism that continues to this day. Other positions Dr. Lord has held include her faculty appointment at the University of Alberta, where she was part of a strong multidisciplinary team of clinicians, and her appointment in child psychiatry at the University of Chicago within a collaborative and clinically skilled group of clinician researchers. During the last 15 years, Dr. Lord has founded two major clinical-research centers, the University of Michigan Autism and

Communication Disorders Center (UMACC), and the Center for Autism and the Developing Brain (CADB) at Weill Cornell Medical College. These centers have served as models for the integration of clinical practice and research, yielding data from thousands of clinically referred and research ascertained individuals with ASD and non-ASD diagnoses. In turn, these data have provided critical information about psychometric properties of numerous assessment instruments, which has informed the modification of existing tools and development of new tools. Dr. Lord has also participated in groundbreaking clinical trials for early treatment and characterization of the disorder within the context of behavioral development and ongoing phenotype-genotype efforts.

Lovaas Approach

Svein Eikeseth

Department of Behavioral Science, Oslo and Akershus University College, Lillestrøm, Norway

Definition

The Lovaas approach was pioneered by O. Ivar Lovaas in the 1970s and 1980s. Lovaas himself used the term “*the UCLA Model*” to describe this treatment. Defining features of the Lovaas approach include:

Behavioral Emphasis. Autism is analyzed in terms of separate behaviors that include excesses (behaviors displayed too often or intensely) and deficits (behaviors that are not displayed often or well enough). Excesses and deficits exhibited by children with autism are addressed using principles of behavior analysis and learning psychology (see “[Treatment Procedures](#)” below).

Family Involvement. Lovaas strongly emphasized family participation because research suggested that parental involvement enabled children to make lasting improvements and carry over these improvements from professional settings, such as special education programs, clinics and hospitals, to the home environment community. To optimize treatment effects, parents are trained to become co-teachers for their child; they learn how to manage the child’s challenging behaviors and how to make the child use the skills he or she has learned from treatment in everyday life.

One-to-One Instruction. During the first 6 to 12 months of intervention, the bulk of the teaching is carried out in a one-to-one setting because it allows for highly individualized teaching and because children with autism may initially learn more readily in such a setting than in groups. The individual instruction focuses on teaching the child key communication, play, and social skills to prepare children to enter group settings.

Integration. When the treatment team determines that the child with autism is ready to enter a group setting, the team chooses a setting where the peers are as typical as possible, as children

with autism often display more appropriate behaviors when integrated with typical peers than when placed in group with other children with autism. A member of the treatment team accompanies the child to the integrated setting in order to help the child be successful (see “[Treatment Procedures](#)”).

Comprehensiveness. The curriculum addresses all three core deficits in autism (i.e., deficits in communication, social skills and social interests, and excess stereotyped and ritualistic behaviors). It also addresses other behavioral excesses and deficits that may be associated with autism such as aggression and self-injurious behavior, attention deficits, learning delays, feeding problems, and difficulties with motor development and self-help skills.

Intensity. Together with treatment method, treatment intensity is perhaps the most important element of the Lovaas Approach. An effective intervention is believed to require highly intensive teaching to allow the child with autism (who also may have intellectual disability) to catch up, as much as possible, with typical peers. Research on the Lovaas approach indicates that 30–40 h per week of one-to-one intervention may be required to produce optimal gains.

Duration. In most cases, practitioners of the Lovaas approach recommend that intervention last for a minimum of two years and may continue for several additional years with a reduced number of hours of one-to-one instruction along with support for participation in school.

Historical Background

The Lovaas approach can be traced back to the late 1950s and the early 1960s, when researchers began using operant principles, derived from the animal laboratory, to address human problems. Ferster and DeMyer (1961) conducted the first study demonstrating the use of operant condition to teach individuals with autism to learn new skills. Later, Wolf, Risley, and Mees (1964) reported the first behavioral intervention to reduce problem behaviors in a child with autism.

From 1965 until 1970, Lovaas and colleagues published a number of seminal studies, reporting the first demonstration of an effective way to teach nonverbal children to speak, a study on establishing social (secondary) reinforcers, a procedure for teaching children to imitate, and several studies on interventions to reduce life-threatening self-injury and problem behaviors.

In 1971, they discovered that many children with autism have a detail-focused learning style, which they called *stimulus overselectivity*, that could hinder the children from acquiring important skills. Also in the 1970s, Lovaas and colleagues presented research showing that stereotyped behavior could be reinforced by the sensory and/or perceptual stimuli produced by the behavior itself (e.g., vestibular and visual stimulation as reinforcement for body rocking). Hence, they used the term “*self-stimulatory*” to describe such behavior.

In 1973, Lovaas and colleagues published their first long-term follow-up study. Twenty children with autism participated. After 12–14 months of behavioral treatment, stereotyped behaviors including echolalia decreased and appropriate speech, appropriate play, and social nonverbal behaviors increased. Some of the children were discharged to a state hospital while others remained with their parents, who had received parent training. Follow-up assessments 1–4 years after the end of treatment showed that children whose parents were trained to carry out the behavioral treatment continued to improve, while children who were institutionalized regressed. After a brief reinstatement of the behavioral treatment, however, the institutionalized children recouped some of their original gains.

From the 1973 follow-up study, Lovaas made six important observations that occasioned what has been labeled the 1987 Early Intervention Project, the landmark study for which Lovaas is best known. First, the youngest children in the 1973 study appeared to make the greatest gains; hence, the 1987 study focused on younger children. Second, treatment effects in the 1973 study were situation specific, and as a result, treatment was moved away from a hospital or clinic setting and into the children’s home and everyday

environment. Third, because response generalization such as becoming more social after learning language rarely occurred, treatment in the 1987 study was designed to target most or all of the children's excess and deficit behaviors. Fourth, some parents became skilled teachers of their children and were the best allies in helping accelerate and maintain treatment gains. Fifth, they offered treatment for most of the child's waking hours, for 2 or more years, and focused on teaching the children to develop friendships with typical peers. According to Lovaas, this therapeutic arrangement was designed to resemble the type of learning environment available to typical children, who learn from their environment from the time they wake up in the morning and until they go to sleep, 365 days per year.

Lovaas's 1987 report indicated that children with autism treated with the Lovaas approach achieved vastly better outcomes than similar children who received little or no such treatment. Lovaas described 9 of the 19 intensively treated children as "normal functioning." In so doing, he challenged the prevailing belief that, although children with autism might be able to learn isolated skills, they would always be delayed and socially isolated. The study sparked passionate debate. While some considered it as a breakthrough, others criticized it and argued that it was an exaggeration to describe the children with the most favorable outcomes as "normal functioning."

In the 1990s, Lovaas built on the 1987 study by co-authoring a long-term follow-up of children in the 1987 study as well as several replication studies.

Rationale or Underlying Theory

In the Lovaas approach, a working hypothesis is that children with autism have a learning deficit that is biologically based and is responsible for the behavioral deficits and excesses exhibited by these children but that can be overcome with specialized instruction. The Lovaas approach directly targets these excesses (e.g., stereotyped behaviors, aggression, and self-injurious

behaviors) and deficits (e.g., communication, play, and social skills) rather than attempting to address some hypothesized underlying conditions or processes or attempting to address "autism" *per se*. Lovaas argued that there is no "magic bullet" in autism treatment and that all behavioral excesses and deficits must be addressed separately.

In the Lovaas approach, the treatment environment should differ as little as possible from the typical educational environment in order to help the child with autism transfer skills to the typical environment and function more successfully in that setting. Lovaas emphasized that typically developing children learn during all waking hours, every day. To approximate this learning environment, and to allow the child with autism to catch up as much as possible with his/her peers, Lovaas argued that an appropriate treatment environment should be in effect most of the day, 7 days per week.

Goals and Objectives

The curriculum is individualized based on each child's needs and stages of development that typically developing children go through but tends to follow a sequence described in teaching manuals and is summarized below:

Beginning Curriculum. Beginning targets include learning readiness skills in the areas of attention, communication, social initiations, and play. Examples include sitting in a chair, responding to simple instructions such as "come here" and "wave bye-bye," pointing, requesting favorite items, joint attention, matching identical objects, imitating gross motor actions or imitating actions with objects, imitating sounds and words, identifying and naming objects, playing independently with toys, and basic turn taking and interactive skills such as rolling a ball to and from an adult.

Intermediate Curriculum. Intermediate targets include further language training such as identification and naming of abstract concepts, parallel play, turn taking, imitating sentences, pre-academic skills such as identifying letters and

numbers, drawing and tracing, and self-help skills such as dressing, toileting, drinking from an open cup, and increasing the range of foods and drink taken.

Advanced Curriculum. Advanced targets include conversation and asking questions, advanced pretend play and cooperative play, social-emotional skills such as theory of mind, advanced academic skills, observational learning, and learning in the classroom environment.

Treatment Participants

The Lovaas approach was developed primarily for children with autism who have mild to moderate intellectual disability and are under the age of 42 months at treatment onset. However, it has been evaluated with other groups, including children with autism and more severe intellectual disability, children with autism who entered treatment up to the age of 7 years, and non-autistic children with intellectual disability.

Several studies have examined relations between intake variables and outcome measures. A meta-analysis published in 2010 by Eldevik and colleagues indicated that the most robust finding to date is a strong positive correlation between treatment intensity and outcome.

Treatment Procedures

Intervention methods build on detailed knowledge of principles and procedures from behavior analysis. *Discrete trial teaching* is a highly structured teaching procedure used to maximize learning. It is used to establish a number of important skills, including cognitive skills, communication, play, social, and self-help skills. The teaching strategy involves (a) breaking skills into small steps, (b) teaching each step of the skill individually until mastered, (c) providing repetitions of teaching steps, (d) prompting the correct skill and fading (removing) the prompts whenever possible, and (e) using reinforcement and stimulus control procedures.

Natural environment teaching is used to teach behaviors in the situations where they routinely occur. During mealtime, for example, the child is reinforced for sitting nicely or instructed how to use a knife and fork appropriately. Whenever possible, the reinforcer is the consequence that naturally follows the target behavior such as going outside to perform a desired activity after practicing tying shoes.

Task analyses and chaining are used to break down complex behaviors (e.g., toy play and language) into smaller units that can be reliably measured and more easily taught. For example, to teach language skills the behavioral components of each skill are identified, and teaching begins with the most basic components such as vocal imitation of sounds. These individual behaviors are then systematically taught and chained together to make one complex behavior.

School integration begins once a range of skills have been acquired that enable the child to access materials, follow the curriculum, and interact with peers in the preschool or school environment. The aim is for a child to learn increasingly from peers, the class teacher, and the school curriculum. Initially, a therapist shadows the child at school, prompting and reinforcing the child for engagement in social interactions and academic activities while implementing behavior support strategies to minimize inappropriate or interfering behaviors. Once the child can follow segments of activities, whole activities, or parts of the full school day, the shadow will then help the child to learn new information and new skills directly from the school environment and not specifically from the one-to-one teaching. For a child who does not learn sufficiently from the classroom environment, the therapist will continue to shadow on a long-term basis and concentrate on integrating the child for activities in which he/she can be successful. Time is also allocated to ongoing one-to-one teaching, both at home and school, during which individual learning goals, including independent living skills, can be addressed more efficiently than in the classroom. To promote each child's independence, shadowing is gradually reduced on a task-specific basis or for periods of the school day.

Efficacy Information

In Lovaas's 1987 study, 19 children received 40 h per week of one-to-one treatment based on the Lovaas approach for a minimum of 2 years. A comparison group of 19 children received 10 h or less per week of the same treatment. A second comparison group of 21 children came from the same agency that diagnosed the majority of the other participants and received community treatment as usual. The mean age at intake was 33 months. When reevaluated at a mean age of 7 years, children in the experimental group had gained an average of 20 IQ points to a mean of 83, and they had made major advances in educational placement. Nine of 19 participants achieved IQ scores of 85 or above and regular educational placement without assistance. In contrast, the two comparison groups showed little change in IQ. The experimental group maintained its gains at a second follow-up conducted when the children averaged 13 years of age.

Similar results have been reported by other investigators, though in some studies the effect sizes were smaller than in the 1987 study. In a meta-analysis, Eldevik, Hastings, Hughes, Jahr, Eikeseth, and Cross (2009) reported effect sizes of 1.10 for IQ change and 0.66 for change in adaptive behavior. By convention, these effect sizes are considered large. However, some investigators have reported somewhat smaller effect sizes.

All studies have reported considerable variability in outcome. A meta-analysis by Eldevik et al. (2010a) sought to determine what proportion of children made clinically meaningful improvements with two metrics: the reliable change index (RCI), which is a measure of how many participants make changes that are statistically significant (unlikely to be due to statistical chance), and the number needed to treat (NNT) in order to have one additional success more than would occur without treatment. The RCI indicated that an IQ gain of 27 points between intake and follow-up was required for statistically reliable change and that 30% of children across studies achieved reliable change in IQ. To achieve reliable change in adaptive behavior, a gain of 21 points was required, and 21% of the participants achieved

this. NNT for IQ was 5, and NNT for adaptive behavior was 7, indicating an effective intervention.

While researchers generally agree that the results of studies have generally been positive, there remains controversy about the scientific quality of the studies, and many have called for additional research with improved research designs.

Outcome Measurement

The most common outcome measures used are IQ, language, and adaptive functioning. The Bayley Scales of Infant Development and the Wechsler Intelligence Scales (WIPPSI or WISC) are the most common IQ tests.

The most widely used instrument to assess language is the Reynell Developmental Language Scales, but due to their severe delays in communication, many participants fail to achieve basal on the Reynell at intake.

To assess adaptive behavior, the Vineland Adaptive Behavior Scales is used.

Some studies have also assessed other domains, such as maladaptive behavior (using the maladaptive scale from Vineland Adaptive Behavior Scales, the Personality Inventory for Children, and the Child Behavior Checklist), school performance (using the Woodcock-Johnson III Tests of Achievement), and changes in diagnosis (using the Autism Diagnostic Interview-Revised (ADI-R)).

Qualifications of Treatment Providers

There are currently no established programs to certify professionals to become competent Lovaas-approach therapists or Lovaas-approach supervisors. Practitioners of the Lovaas approach indicate that, to become a competent therapist, individuals should obtain a bachelor's degree in psychology, education, or social work, with coursework in applied behavior analysis, developmental disorders, and child development. In addition, they require therapists to work at least

three months hands-on with a child in an apprenticeship with a trained therapist. At the end of this training, the therapist must be able to apply the behavioral principles correctly during one-to-one teaching.

To become a supervisor, Lovaas and colleagues have required the practitioner to be an experienced Lovaas-approach therapist and hold a master's degree that includes graduate courses in applied behavior analysis, developmental disorders, and child development. In addition, the supervisors must learn how to conduct staff training, develop and individualize the child's curriculum, and work with families. These skills can be learned through working in an apprenticeship with a competent Lovaas-approach supervisor and by studying available teaching manuals, evidenced-based parent training programs, and typical development. Finally, the supervisor should be supervised by a Ph.D. level clinical psychologist specializing in the Lovaas approach.

Lovaas, O. Ivar

Svein Eikeseth¹ and Tristram Smith²

¹Department of Behavioral Science, Oslo and Akershus University College, Lillestrøm, Norway

²Department of Pediatrics, University of Rochester Medical Center, Rochester, NY, USA

Name and Degrees

Dr. O. Ivar Lovaas received his B.A. in Social Studies from Luther College, Decorah, Iowa, in 1951; an M.S. in psychology from the University of Washington, Seattle, Washington, in 1954; and a Ph.D. in psychology from the University of Washington in 1958.

Tristram Smith: deceased.

Major Appointments

From 1958 until 1961, Lovaas worked at the University of Washington's Child Development Institute as an acting assistant professor. In 1961, he accepted a position as an assistant professor in the University of California, Los Angeles (UCLA), Psychology Department, where he spent the remainder of his career. He became an associate professor in 1965, tenured professor in 1967, and professor emeritus in 2004.

In 1962 Dr. Lovaas founded the UCLA Clinic for the Behavioral Treatment of Children, and between 1972 and 1980, Dr. Lovaas acted as a Research Specialist at Camarillo State Hospital, Camarillo, California.

In 1995, Dr. Lovaas founded the Lovaas Institute for Early Intervention (the LIFE Institute).

Major Honors and Awards

Dr. Lovaas received many honors for his work, including an Honorary Doctorate from Luther College, a Guggenheim Fellowship, the Edgar Doll Award from Division 33 of the American Psychological Association (1994), the California Senate Award (1994), the Research Award from the American Association on Mental Retardation (1994), Distinguished Guest Faculty Award from Ohio State University (1994), a Golden Key Honorary Award (2000), the Distinguished Research Contribution Award from Division 53 of the American Psychological Association (2001), and the California Association for Behavior Analysis award for outstanding contributions to behavior analysis (posthumous, 2011).

In addition, he was an honorary member of a number of organizations including Autism Society of America, the Norwegian Association for Behavior Analysis (NAFO), the Uruguayan Society for Analysis and Behavior Therapy (SUATEC), and the American Board of Medical Psychotherapies.

Landmark Clinical, Scientific, and Professional Contributions

From 1965 and on, Lovaas and colleagues published a number of seminal studies transforming interventions and services for autism. An important initial contribution was the development of an apparatus and recording procedure allowing repeated and reliable measures of deficit language and social behaviors and excess stereotyped, aggressive, and self-injurious behaviors (Lovaas et al. 1965a, b). This recording procedure allowed moment-to-moment assessment of the dependent variables, providing the investigators immediate feedback regarding the effectiveness of various treatment variables. This innovation, together with the use of single subject research designs, facilitated the groundbreaking finding subsequently presented by Dr. Lovaas and colleagues.

From 1965 until 1970, Lovaas and colleagues reported, among other findings, the first demonstration of an effective way to teach nonverbal children to speak (Lovaas, 1966; Lovaas et al. 1966a), a study on establishing social (secondary) reinforcers (Lovaas et al. 1966b), a procedure for teaching children to imitate (Lovaas et al. 1967), and several studies on interventions to reduce life-threatening self-injury and aggression (c.f., Lovaas et al. 1965b) and a pioneering investigation of antecedents and consequences that maintained a problem behavior (Lovaas and Simmons 1969), a forerunner of what is now called experimental functional analysis.

Also in the 1960s, Lovaas and colleagues conducted studies indicating that punishment procedures involving aversives such as mild doses of electric shock could be effective in reducing extreme, sometimes life-threatening aggression or self-injury. By the late 1980s, however, Lovaas felt such procedures had become unnecessary because non-aversive interventions had become so sophisticated and successful that aversives were no longer necessary. Accordingly, he stopped using them at that time.

In 1971, Lovaas and colleagues showed that many children with autism have a learning style

that could hinder them from learning important skills and generalizing these skills outside the intervention setting. This style involved attending to only one element of a complex stimulus (e.g., visual but not auditory components of a stimulus). They called this style *stimulus overselectivity* (Lovaas et al. 1971) and published several additional studies on this topic during the 1970s.

In 1973, Lovaas and colleagues published their first long-term follow-up study (Lovaas et al. 1973). Twenty children with autism participated. After 12–14 months of behavioral treatment, stereotyped behaviors including echolalia decreased, and appropriate speech, appropriate play, and social nonverbal behaviors increased. At the end of treatment, some of the children were discharged to a state hospital, while some children remained with their parents, who had received parent training. Follow-up assessments 1–4 years after the end of treatment showed that children whose parents were trained to carry out the behavioral treatment continued to improve, while children who were institutionalized regressed.

Based on data from this study, Lovaas hypothesized that treatment effects could be optimized if intervention was started *early* in the child's life and if intervention was *comprehensive*, that is, addressing all behavior excesses and deficits exhibited by a particular child. In addition, Lovaas argued that intervention had to be *intensive*; that is, it should provide a learning environment for the child throughout the whole day, be carried out in the child's *natural environment* (such as at home and in school, rather than in an institution), and include persons who are part of the child's natural environment (such as parents, teachers, peers). Finally, Lovaas argued that the children should enter *typical classes* to access typical peers to model appropriate behaviors, rather than attend special classes.

In 1970, Lovaas initiated the UCLA Young Autism Project in order to provide treatment based on these principles. In 1987, he published the first set of results in the landmark study for which he is now best known: the report entitled *Behavioral Treatment and Normal Educational and Intellectual Functioning in Young Autistic*

Children, which appeared in the *Journal of Consulting and Clinical Psychology*. This report indicated that children with autism treated with the Lovaas Approach achieved vastly better outcomes than similar children who received little or no such treatment. Lovaas described 9 of the 19 intensively treated children as “normal functioning” and possibly even recovered. In so doing, he challenged the prevailing belief that, although children with autism might be able to learn isolated skills, they would always be delayed and socially isolated. The study sparked passionate debate. While some considered it as a breakthrough, others criticized it and argued that it was an exaggeration to describe the children with the most favorable outcomes as normal functioning.

Also in 1987, Lovaas and colleagues presented a review of stereotyped behavior (Lovaas et al. 1987), which they called *self-stimulatory* because, they argued, it was maintained by the sensory and/or perceptual stimuli produced by the behavior itself (e.g., vestibular and visual stimulation as reinforcement for body rocking).

In the 1990s, Lovaas built on the 1987 study by co-authoring a long-term follow-up of children in the 1987 study (McEachin et al. 1993), as well as several replication studies. He also obtained two federal grants to support replications by other investigators. He continued to publish important work until he was in his late seventies, notably a revision of his intervention manual (Lovaas 2003).

Short Biography

Lovaas was born on May 8, 1927, in Lier, Norway. His father was a journalist. During the Second World War, Norway was occupied by the Nazis for 5 years (1940–1945). At that time, Lovaas was in his teens, and this experience came to affect Lovaas in many ways. Most importantly, it made him reflect on the “nature versus nurture” issue. He believed that the Germans could not be inherently evil, which in turn, convinced him that the environment could exert highly powerful effects on behaviors.

In 1947, shortly after the Second World War, Lovaas graduated from Gymnasium (high school). In 1950, after serving his military duty in the Norwegian air force as a medic, Dr. Lovaas immigrated to the USA, attending Luther College in Decorah, Iowa, on a violin scholarship. Subsequently, in 1951, he went on to the University of Washington, Seattle, where he stayed for the next 10 years, receiving his M.S. and Ph.D. in psychology and working as an acting assistant professor.

Lovaas’ interest in children with autism came about accidentally. His initial research had been on how a person’s language may influence non-verbal behaviors, a process later described as instructional control or rule-governed behavior. At UCLA, Lovaas sought to extend this research by studying how to teach language to children who had communication delays and testing the effects of improved language on other behaviors such as social interaction. After visiting a clinic for children with autism, he became convinced that he had found the ideal group for this research. Subsequently, at the laboratories at UCLA and Camarillo State Hospital, Dr. Lovaas and colleagues conducted the groundbreaking and pioneering research, which have had tremendous influence on applied behavior analysis (ABA) and services for individuals with autism.

Alongside his research and clinical innovations, Lovaas devoted much of his energy to advocacy on behalf of autism and popularization of ABA. In the 1960s, he helped found the parent organization now called the Autism Society of America. He also became a strong proponent of moving children (and adults) with autism from large institutions into small group homes. Subsequently, as many children in his research successfully entered general education classes in public schools, he also became a proponent of inclusion in these classes.

Lovaas’ popularizations included one of the first films on ABA, produced in 1969, to show interventions for teaching language to children with autism. Lovaas also published two of the first ABA intervention manuals in 1977 and 1981. These manuals laid out how and what to teach, thereby making ABA accessible to many families and providers. Always quotable and not

shy about extolling the benefits of ABA, Lovaas was profiled in many media outlets such as *Life*, *Rolling Stone*, the *New York Times*, and the *CBS Evening News*. He was also a popular instructor, introducing generations of students to autism and ABA.

He is survived by his wife, Nina Lovaas, four children from his first marriage, six grandchildren, and three great-grandchildren.

Lovaas died at the age of 83 on August 2, in Lancaster, California, 2010.

Low Registration

Winifred Schultz-Krohn
Department of Occupational Therapy, San José
State University, San José, CA, USA

Definition

This term refers to the individual's limited ability to notice or respond to important or salient

sensory information. Although Ayres discussed “registration of sensory information,” the term “low registration” was not included in her writings about sensory integration. The term “low registration” is used in the sensory processing literature and is clearly defined by Dunn (2007) as a pattern of sensory processing where the individual has a high threshold to sensory experiences and does not notice or detect changes in sensory situations at the same rate of others. The individual may appear passive in response to changes in sensory intensities due to limited detection of those changes. Individuals who have low registration of sensory experiences benefit from occupational therapy services designed to enhance sensory processing and improved ability to detect and respond to changes in sensory experiences.

Speech-Language Pathology Program, University of Texas at El Paso College of Health Science, El Paso, TX, USA

Synonyms

[Low-tech augmentative and alternative communication \(AAC\)](#); [Low-tech system](#)

Definition

Although there are differing opinions regarding the precise definition of augmentative and alternative communication (AAC) systems, technically, a low-technology (low-tech) AAC device is one that requires a power source such as a battery to operate and is very easy to program. A no-tech system is any communication device that does not require a power source. An example of a no-tech system is a picture communication board. Examples of low-tech systems are the BIGmack[®], LITTLEmack[®], Step-by-Step Communicator[®], and the SpeakEasy[®] which are sold by AbleNet. See Beukelman and Mirenda (2012) for a full description of low-technology devices and their implementation.

Luria-Nebraska Neuropsychological Battery

Eva Troyb¹ and Deborah Fein²

¹Neuropsychology, EASTCONN Regional Education Service Center, Columbia, CT, USA

²Department of Psychological Sciences, University of Connecticut, Storrs, CT, USA

Description

The Luria-Nebraska is a neuropsychological evaluation battery that was developed to uncover the presence of cognitive impairments and to locate focal brain abnormalities that may account for these impairments in individuals 15 years of age and older. The battery consists of 11 clinical scales assessing major areas of neuropsychological functioning (motor functions, rhythm, tactile functions, visual functions, receptive speech, expressive speech, writing, reading, arithmetic, memory, and intellectual processes), two sensorimotor scales (left hemisphere, right hemisphere), and three summary scales (pathognomonic, profile elevation, and impairment). A parallel form of this battery is available and includes an additional clinical scale that evaluates delayed recollection of previously administered memory items (intermediate-term memory scale). Since publication, other scales have been developed and made available to users, including 8 localization scales and 28 factor scales, some of which include few items and must be interpreted with caution (Lezak et al. 2004). Administration time usually lasts 2–3 h. Charles Golden developed a version of this battery for use in children aged 8–12 years (Golden 1981). It uses the same test stimuli with some additional materials (see Lark 2004 and Golden 2011, for reviews of the children's revision of the Luria-Nebraska).

Historical Background

The Luria-Nebraska was published between 1980 and 1985 and was initially known as the Luria-Dakota Neuropsychological Battery during its development. The battery was based on the evaluation techniques practiced by Alexander Luria, which were compiled and organized into test items by Anne-Lise Christensen. The development of the test was based on the principle that behavior consists of sensory, cognitive, and behavioral processes, and disruptions in any of these domains may lead to impairments in behavior. As a result, tasks assessing each area of processing were selected from Christensen's collection by Golden and colleagues, and items that best discriminated between healthy and neurologically impaired individuals were included in the battery.

Psychometric Data

Reports of internal consistency coefficients for the measure range between .40 and .94, with most in the .80s, while test-retest reliability and interrater reliability for all of the scales have been reported to fall between .80 and .95 (Golden et al. 1985). Several factor analytic studies support the factor structure proposed by the authors (Moses 1984a, b, c). Validation of the measure has depended on studies suggesting that this measure can accurately discriminate healthy adults from adults who have suffered a brain injury (Golden et al. 1985; Kane et al. 1985; Moses et al. 1983). However, many of these studies included patients with moderate to severe impairments. Some have argued that the Luria-Nebraska includes tasks that most adults can complete successfully unless they are severely impaired or relatively low functioning, and as a result this battery may be less useful in identifying mild deficits among high-functioning individuals (Adams 1980, 1984; Delis and Kaplan 1982; Lezak et al. 2004). Furthermore, the Luria-Nebraska does not appear to accurately localize the laterality of lesions, particularly among patients with aphasia (Delis and Kaplan 1982; Goldstein et al. 1987; Ryan et al. 1988; Sears et al. 1984).

Clinical Uses

Golden et al. (1982) cautioned against the use of the Luria-Nebraska among professionals who did not receive training in neuropsychology, neurology, and Luria's testing approach. The authors of the battery also reminded users that the results should depend upon scores obtained on the scales of this battery, patterns of responses, behavioral observations, and hypothesis testing. Many neuropsychologists have also cautioned against using this measure beyond the diagnosis of a moderate to severe neurological impairment (Adams 1984; Crosson and Warren 1982; Delis and Kaplan 1982; Spiers 1984). The test was developed at a time when neuropsychologists were being asked to identify the presence, side, and location of lesions; however, this is much less relevant in the current age of advanced imaging techniques.

Luxembourg and Autism

Andreia P. Costa and Georges Steffgen

Institute for Health and Behavior, University of Luxembourg, Esch-sur-Alzette, Luxembourg

Historical Background

Luxembourg is a small trilingual (Luxembourgish, French, and German) European country with an estimated population in July 2017 of 594,130 inhabitants. It is however, the country in Europe with the highest population growth rate and the highest net migration rate (Central Intelligence Agency 2017).

There are no official figures as to the prevalence and incidence of autism in Luxembourg. However, according to the most recent statistics provided by Autism-Europe, autism spectrum disorder affects around 1 in 100 people (Autism-Europe 2017). Therefore, it is estimated that approximately 5,900 people live in Luxembourg with a disorder in the autism spectrum. With Luxembourg’s birth rate at 11.5/1000 (Central Intelligence Agency 2017), it can also be estimated that 68 new cases of autism appear each year in the country.

Services dedicated to people with autism started to appear in Luxembourg in the 1980s and have since then increased substantially. The first organization dedicated to autism in Luxembourg was established in 1981 by the initiative of Gilbert Huyberegts, the father of a child with autism and later also the president of Autism-Europe (from 1989 to 2000). This not-for-profit organization, the *Société Luxembourgeoise pour l’Aide aux Personnes Autistiques* [Luxembourgish Society for the Help of Autistic People], which in 1996 changed its name to *Autisme Luxembourg asbl*, was composed of parents, professionals, and supporters. This society had as its aims to create, develop, and manage preventive and curative measures, as well as to put in place educational and accommodation centers, and to search for a continuous integration of people with autism.

To fulfill one of its aims – to develop educational measures for people with autism – the *Société Luxembourgeoise pour l'Aide aux Personnes Autistiques* created in 1982 educational classes for children with autism within a mainstream elementary school. This initiative was audacious at a time when disabled children attended exclusively special education schools. In 1988, the government created an educational structure, the *Institut pour Enfants Autistiques et Psychotiques* [Institute for Autistic and Psychotic Children] and the classes became part of the *Service de l'Éducation Différenciée* [Special Education Service] of the Ministry for National Education. However, most of the classes remained as they were since the beginning – in mainstream schools. The aim of the *Institut* was to provide children and adolescents with autism with an adequate education, social, and professional integration. For this, the special education classrooms insured an education adapted to their needs and implemented speech and psychomotor therapy.

To foster the personal development of people with autism, in 1989 the *Société Luxembourgeoise pour l'Aide aux Personnes Autistiques* also created the *Centre d'Intégration et de Récréation pour Personnes atteintes d'Autisme* (CIRPA) [Integration and Recreation Center for People with Autism] which offered specialized assistance and support to the needs and capacities of people with autism across their life through the organization of daily activities. In addition to the CIRPA, and to respond to a need of professional development of adults with autism, in 1991 the *Société Luxembourgeoise pour l'Aide aux Personnes Autistiques* created the cooperative society *Peter Pan*, which promoted the training and social integration of adults with autism in a protected work environment. The cooperative society *Peter Pan* has since then been dissolved.

Led by the initiative of Gilbert Huyberegts and a group of parents of children with autism, in 1996 the *Fondation Autisme Luxembourg* [Autism Luxembourg Foundation] was created with the support of the *Société Luxembourgeoise pour l'Aide aux Personnes Autistiques*. The *Fondation Autisme Luxembourg* had as aims to develop the capacities of autistic people and

to provide them with a dignified life. To achieve this, they set as aims to (a) create, develop, and manage preventive and curative measures such as educational and accommodation centers for children, adolescents, and adults with autism; (b) facilitate the integration of people with autism in all educational, socio-cultural, and professional domains; (c) create and maintain a consultation service as well as a center for training and information for the parents of people with autism; and (d) facilitate research on autism.

In 2000, a not-for-profit parental association, the *Association des Parents de Personnes Atteintes d'Autisme de Luxembourg* [Association of Parents of Persons with Autism from Luxembourg], was created to protect the rights of people with autism and their families and to help and support them. Additionally, the association aimed to improve the care services of people with autism throughout their life by facilitating and accentuating the dialog between families and policy makers and to sensitize the general public to better integrate people with autism in the educational, socio-cultural, sportive, and professional domains.

As one of the most recent measures put in place to improve the services offered to people with autism and their families, in 2009 the *Unité Autisme* [Autism Unit] was added to the services proposed by the *Service National de Pédiopsychiatrie du Centre Hospitalier du Luxembourg* [National Service of Child Psychiatry from the *Centre Hospitalier du Luxembourg*]. The service exists since 1995 and includes a consultation unit, a hospitalization unit, and a day care center. The aim of the creation of the *Unité Autisme* was to diagnose autism, support the families, and provide continued care for young children with autism.

Legal Issues, Mandates for Service

In Luxembourg, there are no laws or mandates specific to autism. However, there have been several laws and legal measures that have had an impact on the rights and quality of life of people with autism.

Regarding education, two laws had a major impact for people with autism. In 1973, a law was approved for the right of disabled children, who could not attend mainstream schools, to receive education at a special education school. Until that law was voted, disabled children were often excluded from receiving a formal education. In 1994, the law of 1973 was modified to encourage as much as possible the inclusion of disabled children in mainstream education. Under these laws, children with autism have the right to a formal education and can receive their education either at a special education school, such as the *Institut pour Enfants Autistiques et Psychotiques*, or at a mainstream school, or share their weekly school time between special and mainstream education. At the mainstream education, special arrangements such as having the support of a special education teacher in the classroom for a certain amount of hours per week is also an option. Upon request of the teacher or the parents, an inclusion commission recommends the type of education best indicated for the child. However, parents have the final decision regarding the type of education and care that their child will receive.

Regarding health care, the law of 1998 and its amendment in 2005 addressing the creation of a dependence care insurance has had a major impact on the services and type of care people with autism can receive from the government. In order to receive special care from the dependence insurance, four main conditions need to be met: (a) to be dependent (i.e., to need help for personal hygiene, nutrition, and mobility), (b) to need the assistance for at least 6 months, (c) to required assistance for at least 3.5 h per week, and (d) that the need for assistance is a consequence of illness. The *Cellule d'Évaluation et d'Orientation de l'Assurance Dépendance* [Evaluation and Orientation Unit from the Dependence Care Insurance] assesses requests, advises regarding the existence of dependence, and determines the care and support provided to the person or the caregiver at different levels. The intensity of care and support is adapted according to the level of dependence of a person on someone else. Children younger than 8 years old are compared to a

developmental chart corresponding to autonomy capacities acquired at different ages. Children older than 8 years old, adolescents, and adults are compared in terms of autonomy to an adult. The support can be reflected, among other things, on the attribution, substitution, reduction, or increase of the support given; on the proposal of reeducation or re-adaptation measures; on the type and amount of professional care provided; on the monetary support given to finance support not provided by a professional service; and on the support given to the family or caregivers.

Concerning the work conditions of adults with autism, two laws have had an impact on the employability and fair compensation of work. In 2003, a law was approved regarding the right of disabled people to work and to receive a salary equivalent to the national standards. Under this law, people with autism, presenting difficulties which impair their employability, should receive at least the national minimum wage or the standard salary for the type of work performed that it be in sheltered workshops or in the mainstream job market. Based on an evaluation by the Medical Commission and the advice of the Orientation Commission, the government pays a part of the person's salary equivalent to the assessed percentage of the person's handicap and the remaining is paid by the employer. In 2011 the law of 2003 was amended to stipulate that the government pays the totality of the salary of a disabled person working in sheltered workshops. Additionally, under these laws, the Orientation Commission can decide whether a person with autism can receive free of charge support in orientation, training, re-education, professional integration and reintegration, initiation to the job market, and support for apprenticeships.

Finally, regarding special juridical statuses of disabled people, the law of 1982 on the rights of incapacitated adults provides legal protective measures for people who due to a reduction of their mental capabilities are unable to comply with legal acts. The law foresees three protective regimes (from less to more protective measures): (a) safeguard justice clauses, (b) advice and support by a legal guardianship, and (c) representation by a legal guardianship.

Overview of Current Treatments and Centers

In Luxembourg, services and centers dedicated to people with autism and their families are nowadays varied and spread through the individual's entire lifespan. They range from diagnostic services, treatment and support measures, education, professional integration and training, leisure activities, assistance, and housing. Due to the small size of the country, services are nationally governed and common to the whole country. Services are often centralized around the country's capital but some services have branches in different regions to facilitate access to people.

Diagnosis

There are two institutions that diagnose autism in Luxembourg. The *Unité Autisme* at the *Centre Hospitalier du Luxembourg* diagnoses children until the age of 6 years and prioritizes the early diagnosis of children before the age of 18 months using a neurodevelopmental and environmental approach. To achieve this, the unit is active in bringing awareness about autism to professionals. They provide training to pediatricians as well as to professionals working in services dedicated to early screenings of children's health and development. This collaboration enables an early screening of autism and families are redirected towards the *Unité Autisme* for further assessments and orientation. In 2016, the *Unité Autisme* had 37 new cases for consultation (Unité Autisme 2017). The *Fondation Autisme Luxembourg* performs autism diagnosis to children, adolescents, and adults using a multidisciplinary approach and with a variety of psychological, educational, functional, and medical assessments. The *Fondation* is also often asked to verify previously obtained diagnosis. In 2016, the *Fondation* performed 37 new diagnostic assessments, from which 17 were diagnosed in the autism spectrum, 11 did not fulfill the criteria for an autism diagnosis, and the remaining 9 were ongoing assessments (Fondation Autisme Luxembourg 2017).

Treatment and Support

Both the *Unité Autisme* and the *Fondation Autisme Luxembourg* additionally provide support and guidance to the families by offering services themselves and by re-orienting families to other services. The *Unité Autisme* offers group psychotherapy for children and therapeutic interviews with the families. In 2016 the *Unité Autisme* followed 141 children and their families (Unité Autisme 2017). The *Fondation Autisme Luxembourg* offers support to children, adolescents, and adults with autism regardless of their abilities or difficult behaviors, as well as to their families and professionals working with them. This psychosocial and psychoeducational support comprises home help and advice to parents on strategies to implement at home, learning resources, and individual assistance on hygiene, mobility, and nutrition. They also work with siblings and peers, and frequently offer information sessions about autism to professional working with people with autism. Additionally, the *Fondation* helps families in the setting up of medical care, obtaining assistance from the care insurance and other allowances that are foreseen in Luxembourg's health and social systems, as well as in obtaining appropriate care through other existing services. In 2016, the *Fondation* received 469 requests for support throughout its service in "diagnosis, support, and training" comprising new and follow-up cases as well as requests from professionals (Fondation Autisme Luxembourg 2017). Since 2010, an increase of about 20% in requests for diagnosis is observed each year and more than 40% of the requests concern people with autism without intellectual disability.

Education

In the education side, the *Institut pour Enfants Autistiques et Psychotiques* currently insures the education of 71 children and adolescents with autism aged from 4–18 years old at different educational levels, who due to their specific learning needs cannot attend mainstream education classrooms. The main aim of the *Institut* is to be as inclusive as possible and is thus composed of 11 different classrooms from which the majority are special education classrooms integrated within

mainstream education schools. There are five classes in elementary schools and two classes in secondary schools. Additionally, there are four professional propaedeutic classes at the *Institut* that provide training preparing students older than 12 years for a profession. Students with autism who do not attend special education classes can also receive support for their special needs within the mainstream educational system. At the elementary school level, this support can be obtained by having special education teachers working in the classroom with the child. This teacher works in close collaboration with the other teachers and the parents. At the secondary school level, an inclusion commission advises adaptations for the student's needs such as technological or person support in class and develops an individualized education program in consortium with the teachers and parents when the student is not able to follow the regular academic program rhythm. With a restructuring of the Special Education System, the *Institut* will change its name to *Centre pour le développement des enfants et jeunes présentant un trouble du spectre de l'autisme* [Center for the development of children and youth with an autism spectrum disorder] and will become one of eight Specialized Psychopedagogy Competence Centers in Luxembourg. This center will provide a specialized and multidisciplinary educational support with trained professionals to children and youth with autism.

Professional Integration and Training

There are different services in Luxembourg to support the professional development of people with autism. The *Fondation Autisme Luxembourg* offers a small educational farm and five sheltered workshops to those who use their day care centers: the kitchen, the laundry, the garden, the do-it-yourself workshops, and sports. These activities ensure learning retention and development of competences, promote verbal and non-verbal communication, provide a stimulating daily social environment, and a commendable daily work activity. These activities are dedicated to people with autism aged 16 years or older who due to their difficulties and challenging behaviors cannot work in other existing

sheltered workshops. Additionally, the *Fondation* is active in the integration of people with autism in the regular job market by providing support in the process of hiring, providing training to the company, as well as coaching those looking for a job.

Autisme Luxembourg asbl offers professional training for people with autism older than 16 years old, who have finished their compulsory school or who have difficulties finding a job due to their needs. An individualized training program is established based on the needs of the persons and prepares them for a professional activity. The training lasts 2–3 years and aims at the acquisition and improvement of personal skills, autonomy, as well as teaching appropriate attitudes and behavior during work. The training prepares people with autism for an active work life either in a sheltered environment or in the regular job market. *Autisme Luxembourg asbl* also offers different sheltered workplaces for people with autism who can work in a variety of domains such as the development of books and mobile applications, digitalization of printed documents, printing shop, gardening, art and ceramics, cooking, etc. People with autism who integrate the regular job market can also receive assistance to find and keep a job from *Autisme Luxembourg asbl* through their ambulatory intervention center. This service aims at providing social support on an as-needed basis to individuals with autism who live independently or semi-independently.

Leisure Activities

Regarding leisure activities, both the *Fondation Autisme Luxembourg* and *Autisme Luxembourg asbl* offer adapted activities to people with autism of different ages. The *Fondation Autisme Luxembourg* offers on a daily basis during the entire year extracurricular activities for children. These include indoor activities such as crafts, cooking, individual desk-based learning, sensory space, games, and relational games or outdoors activities such as walks, swimming, visits to parks, and attendance to shows. The *Fondation* also organizes regular holiday camps for people with autism of all ages (children, adolescents, and adults) throughout the entire year.

In their day care center and leisure center, *Autisme Luxembourg asbl* offers adults with autism who are not able to exercise any professional activity different occupational activities such as games and puzzles, sportive activities such as walks and swimming, socio-pedagogical and therapeutic activities such as snoezelen and musical sessions, as well as regular outings.

Assistance

Social, physical, and mental health assistances are provided by the *Fondation Autisme Luxembourg* throughout their different services such as the support service (see “[Treatment and Support](#)” section).

Autisme Luxembourg asbl provides a home help service to keep people with autism in contact with others and to help them build a social network of support with the aim of maximizing their autonomy and well-being. They also provide a care and health service that helps centralize their information and manage the contact between the person with autism, their families, and different health-care providers (dentist, psychiatrist, physical therapist, psychotherapist, etc.). Finally, a consultation service is also offered which is composed of a multidisciplinary team that develops interventions in the form of consultations, interviews, individual therapy sessions, group therapy sessions, information sessions, and work with the families.

Housing

Currently, the *Fondation Autisme Luxembourg* has two residential centers for people with autism. One of the centers has three homes that accommodate 20 people with autism aged from 20 to 65 years living in small groups. The other residence accommodates 24 people with autism presenting with different levels of independence, living in three groups of 6–7 people each. In this center, one of the homes is generally dedicated to individuals aged 20–60 years, another home is specifically dedicated to elderly people who have reduced mobility, and the other is specifically dedicated to younger people with autism

such as adolescents. Both centers have permanently at least two respite care rooms for temporary admissions to meet the needs of families when required and for emergency cases when needed. This service is available for people with autism of all ages and levels of abilities regardless of their degree of difficult behaviors.

Autisme Luxembourg asbl offers three types of housing support for adults with autism. They have three centers for supported housing in which residents live autonomously and the association insures through their home help service that the person stays in contact with others in their community and neighborhood, helping their integration, autonomy, and well-being according to their abilities. *Autisme Luxembourg asbl* also has a residence for five people who either work in their sheltered workshops or who attend the day care center. The stay at this residence is intended as a transition period where residents are prepared to a more autonomous life where they can manage their budget and take care of themselves and the place where they live. Finally, *Autisme Luxembourg asbl* also has a residence for substantially dependent people with autism. That residence houses ten people who need a close socio-pedagogical support in their daily life activities. The residence also includes one respite care unit for emergency cases.

Other Non-autism Institutions

In addition to the different services that are dedicated exclusively to people with autism, there are also other institutions and services in Luxembourg dedicated to support people with educational difficulties or disabilities, who can provide help to those with autism. In the support of young children, the *Service de Rééducation Précoce – Hëllef fir de Puppelchen* [Early re-Education Service – Help for the Babies] provides services of observation, assessment, screening, guidance, treatment, and reeducation to children up to the age of 4 years. Their multidisciplinary team offers physical, occupational, and speech therapy as well as playgroups to improve children’s autonomy and psychosocial abilities. The *Service d’Intervention Précoce Orthopédagogique*

[Service of Early Intervention and Orthopedagogy] provides services to children up to the age of 6 years on psychological assessment and testing of abilities, difficulties, and delays, as well as socio-pedagogical and therapeutic support, and psychological interventions for the children and their parents. Additionally, parents can seek treatment, therapy, and support, as well as diagnostic advice on autism from private sector professionals such as pediatricians, psychiatrists, and psychologists.

Associations such as the *Tricentenaire asbl*, the *Association de Parents d'Enfants Mentalement Handicapés* [Association of Parents of Mentally Handicapped Children], the *Ligue HMC*, or companies such as *elisabeth* that act in the social domain provide therapeutic support, day care centers, leisure activities, housing, professional training, and sheltered work structures to disabled people. Finally, *Info-Handicap Luxembourg* informs, orients, and provides support to disabled people, their families, and professionals. The service also provides legal assistance to support people in the access to services, to protect their rights, and to assist them in case of discrimination.

Overview of Research Directions

A research group conducts research on autism at the *Institute for Health and Behavior* at the *University of Luxembourg*. The research is centered on understanding different aspects related to the emotional difficulties of children with autism (e.g., Costa et al. 2017c) and the link between these to the development of internalizing and externalizing problems as well as to difficulties within the family (e.g., Costa et al. 2017a). The group is currently working on the development of technology-based interventions to teach emotional ability to children with autism (e.g., Costa et al. 2017b). Additionally, other works such as Bachelor's and Master's theses about autism have been conducted in collaboration with the University of Luxembourg as well as with other institutions in Luxembourg.

Overview of Training

The *Fondation Autisme Luxembourg* provides training to professionals working with people with autism as well as to parents and interested persons. The *Fondation* also offers the "Earlybird" training under the license of the National Autistic Society from the United Kingdom, to parents of children with autism under the age of 6 years. Training sessions are organized on a regular basis and are provided either at the *Fondation* or in the framework of the trainings offered by the *Institut de Formation de l'Éducation Nationale* [Training Institute from the National Education]. The *Fondation* also acts as a training platform for people learning to become social workers and the trainings provided by the *Fondation* are governmentally recognized. Additionally, the *Fondation* organizes regular parent-professional meetings where parents are informed of state-of-the-art practices and advances related to autism and where parents can ask questions and exchange information with professionals. In these meetings, people with autism without intellectual disability often take part as trainers or facilitators of the training sessions. In addition, the *Unité de Formation et d'Éducation Permanente* [Training and Permanent Education Unit] also offers training to professionals working with people with disabilities, specifically in the social and support domains.

Social Policy and Current Controversies

Currently, the main challenges about autism in Luxembourg are related to parents' and professionals' concerns regarding a more comprehensive and clearly structured care of people with autism. The services have substantially increased since the 1980s and different structures now exist to support people with autism and their families. However, some aspects still need to be considered in order to further develop the offered support and services.

One of the challenges, from which some of the others stem, is a need for an overview

regarding the situation of autism in the country. Autism prevalence and incidence in Luxembourg is unknown and a comprehensive system reporting the education and care that diagnosed people receive is still to be developed. Related to that issue, is a difficulty in the concertation of efforts among the different institutions dedicated to autism. Institutions cooperate among themselves to provide the better care for the person and the family but the absence of a national plan for autism, as is the case for many European countries and is the case for other societal challenges in Luxembourg such as suicide prevention and rare diseases, makes it difficult for the institutions to develop a long-term service adapted to the real needs of the country and coordinate their efforts.

Additionally, a common problem faced by the different institutions is a lack of resources to deal with the increasing number of people requesting a diagnosis and the diagnosed who need care and adapted structures. Even though several structures exist, they are not sufficient for all those requiring support. There is a long waiting list for diagnosis and an early diagnosis, even though given priority, cannot always be guaranteed. This hinders the implementation of early interventions which are a determinant factor to the outcomes of the child and the family. Furthermore, there are no intensive intervention programs dedicated to work on children's abilities that can foster their development and increase the chances of better life outcomes and well-being. There are also a limited number of structures and places that provide adapted support, care, and accommodation to people with autism which cannot answer to all the requests. For instance, a living structure able to accommodate children and adolescents with autism with severe behavior problems, which can cause significant distress and loss of economic power to the family due to the need of a parent remaining constantly at home, is still inexistent.

In Luxembourg, different services, structures, and measures have been developed in the past decades that had an impact in improving the lives and well-being of people with autism and their families. Nowadays, the country strives to

continue to provide quality services that are accessible to all people with autism and their families. To achieve this and answer to the needs of Luxembourg's growing population more services as well as the scope of the existing ones need to be expanded.

Description

The CDIs (Fenson et al. [2007](#)) are a set of parent-informant measures designed to evaluate the

communicative skills of young typically developing children from their “early signs of comprehension, to their first nonverbal gestural signals, to the expansion of early vocabulary and the beginnings of grammar” (Fenson et al., p. 7). To accomplish this, two separate forms were developed. These are the *CDI: Words and Gestures* and the *CDI: Words and Sentences*.

The *CDI: Words and Gestures* is designed for typically developing children ages 8–18 months as a measure of emerging receptive and expressive vocabulary and the use of communicative or symbolic gestures. It has two major parts. Part I, Early Words, is divided into four sections. Section A, First Signs of Understanding, includes three yes-no items (e.g., “[Does your child] respond when name is called?”) intended to determine whether the child has started to respond to language. Section B, Phrases, is a 28-item checklist designed to tap the understanding of everyday language in the context of interactional routines (e.g., “Don’t touch”). Section C, Starting to Talk, consists of two items to assess the frequency (i.e., never, sometimes, often) with which a child imitates words and labels objects. Section D, the largest section, is called the Vocabulary Checklist. It is a 396-item checklist organized into 19 semantic categories. Ten of these reflect different noun classes, but a variety of other categories are also represented (e.g., verbs, adjectives, pronouns, quantifiers). For each item, the respondent indicates whether the child “understands” and/or “understands and says.”

Part II, Actions and Gestures, is divided into five sections. Section A, First Communicative Gestures, includes 12 items to assess the frequency (i.e., never, sometimes, often) of nonverbal communicative intentions (e.g., reaching, pointing, nodding). Section B, Games and Routines, is comprised of six yes-no items (e.g., “playing peekaboo”). Section C, Actions with Objects, uses 17 yes-no items (e.g., “eat with a spoon or fork”). Section D, Pretending to be a Parent, includes 13 yes-no items where respondents indicate the kinds of actions a child engages in during pretend play with a stuffed animal or doll (e.g., “Kiss or hug it”). Section E, Imitating Other Adult Actions, includes 15 yes-no items (e.g., “wash dishes”) intended to assess the child’s attempts to simulate the actions of adults using real or toy implements. A table summarizing the content of the *CDI: Words and Gestures* form is presented in Table 1.

Unlike the *CDI: Words and Gestures* form which is designed to evaluate receptive and expressive language, the *CDI: Words and*

Sentences form is intended to assess expressive language only. It is designed for typically developing children ages 16–30 months as a measure of developing expressive vocabulary and a number of aspects of early grammar development. Part I, Words Children Use, is divided in two sections. Section A, Vocabulary Checklist, is a 690-item checklist organized into 22 semantic categories. The categories are similar to those used in the CDI: Words and Gestures form except some categories are further divided and two categories are added (i.e., helping verbs and connecting words). For each item, respondents simply indicate those items the child “says.” Section B, How Children Use Words, includes five items to assess the frequency (i.e., never, sometimes, often) with which a child talks about things and people that are not in the here and now (e.g., talking about an absent toy, pet, or person). Part II, Sentences and Grammar, is divided into five sections. Section A, Word Endings/Part 1, uses four items to assess the frequency (i.e., not yet, sometimes, often) with which the child produces early emerging morphemes that

MacArthur-Bates Communicative Development Inventories, Second Edition, Table 1 Communicative development inventory: words and gestures

	Description	Example
<i>Part I: early words</i>		
A. First signs of understanding	General items about early comprehension of familiar words and phrases (3 items)	Child responds to his/her name
B. Phrases	Comprehension of everyday phrases and routines (28 items)	Responding to “don’t touch”?
C. Starting to talk	Imitation and labeling (2 items)	i.e., imitating words and naming objects
D. Vocabulary checklist	A 396-item checklist organized into 19 semantic categories with separate columns for comprehension and production	Vroom, moo (sound effects and animal sounds), bear (animals names), ball (toys)
<i>Part II: actions and gestures</i>		
A. First communicative gestures	Nonverbal communicative and intentional behaviors (12 items)	Reaching, pointing, nodding
B. Games and routines	Engagement in games/interactional routines (6 items)	Playing peekaboo
C. Actions with objects	Acting upon objects in conventional ways (17 items)	Eating with a spoon or fork?
D. Pretending to be a parent	Pretending to care for stuff animal or doll in a parental manner (13 items)	Kissing or hugging a doll
E. Imitating other adults actions	Attempts to simulate adult activities with real or toy implements (15 items)	Washing dishes

appear at the end of words (i.e., plural -s, possessive -s, present progressive -ing, regular past tense -ed). Section B, Word Forms, is a checklist of 25 items intended to tap production of irregular nouns (e.g., children) and verbs (e.g., ate). Section C, Word Endings/Part 2, is a 31-item checklist of overregularized nouns (e.g., child) and verbs (e.g., ated) which occur naturally in children's speech and indicate increasing linguistic sophistication. A single question (combining) then asks whether the child has begun to combine words (not yet, sometimes, often). Section D, Examples, is intended to provide a basis for estimating mean length of utterance (MLU). Here, the respondent is asked to write three examples of the longest sentences that the child has said recently. Section E, Complexity, is a 37-item checklist designed to assess syntactic complexity. Each of the 37 items is comprised of a pair of sentences that contrast in complexity (e.g., "two shoe" versus "two shoes," "turn on the light" versus "turn on the light so I can see"). Using a forced-choice

format, respondents are asked to judge which sentence in each pair sounds most like the way their child talks. A table summarizing the content of the *CDI: Words and Sentences* form is presented in Table 2.

Detailed administration and scoring procedures (with examples) are provided in the technical manual, and comprehensive descriptive data are presented for all CDI sections. Separate percentile rank data for boys and girls using 1-month intervals are provided for all sections except two sections of the CDI: Words and Gestures form (i.e., First Signs of Understanding, Starting to Talk) and two sections of the CDI: Words and Sentences (i.e., How Children Use Words, Word Endings/Part 1). When percentiles are not provided, the percentage of affirmative answers is calculated for comparison with the percentages given in the manual. When percentiles are provided, they can be unstable. Specifically, restriction in the range of scores sometimes occurred for ages at which the skills in question were just

MacArthur-Bates Communicative Development Inventories, Second Edition, Table 2 Communicative development inventory: words and sentences

	Description	Example
<i>Part I: words children use</i>		
A. Vocabulary checklist	A 680-item checklist organized into 22 semantic categories with column for production only	Moo (sound effects), tiger (animals), coat (clothing), when (question words)
B. How children use words	Use of language to refer to the past, future, and absent people and objects (5 items)	Talking about an absent toy, pet, or person
<i>Part II: sentences and grammar</i>		
A. Word endings/part 1	Use of plural -s, possessive -s, present progressive (-ing), and regular past tense (-ed) (4 items)	Shoes, Daddy's, running, opened
B. Word forms	A list of irregular plural nouns (5 items) and irregular past tense verbs (20 items)	Children, men, fell, heard
C. Word endings/part 2	A list of overregularized nouns (14 items) and overregularized verbs (31 items)	Foots, ated
Combining	A question about whether the child has begun to combine words (1 item)	i.e., Has the child begun to combine words?
D. Examples	A request to write examples of the three longest sentences that the parent has heard the child say in the recent past (basis for the mean length of utterance)	n/a
E. Complexity	Sentence pairs that contrast in length and grammatical complexity (37 items pairs); asks the parent to indicate which one sounds most like the way the child currently talks	Go bye bye versus wanna go bye bye

emerging. When this happens, small differences in raw scores can have dramatically different effects on percentile ranks. As Fenson et al. (2007) explain:

Because relatively few items can have such a large effect on the child's percentile scores in these instances, users should be very cautious in drawing strong conclusions based on these reported values. (pp. 33–34)

The original and expanded versions of a Basic Information Form are included in the CDI. The forms are designed to gather demographic information useful in interpretation of test scores. The expanded version also contains several questions regarding child health history. Each CDI form takes between 20 and 40 min to complete. It should be noted that CDI short forms are available (Fenson et al. 2000). Although these may be useful to researchers and professionals who seek a quick assessment of early language, the short forms likely lack the precision of the full CDIs and must be administered and interpreted with caution (Fenson et al. 2007). Members of the CDI advisory board have developed Mexican Spanish versions (including short forms) of the CDIs (Jackson-Maldonado et al. 2003). The measures have also been developed in a number of languages other than English by other researchers. A comprehensive list of these versions is available on the CDI web site (<http://www.sci.sdsu.edu/cdi/adaptations.htm>).

Historical Background

As Fenson et al. (2007) explain, the first systematic attempts to use questionnaires to tap parents' knowledge of their children's language skills were conducted by Elizabeth Bates (a codeveloper of the CDIs) and colleagues in the 1970s and 1980s (e.g., Bates et al. 1975). These inventories were later refined to tap parents' knowledge of their children's vocabulary and grammar and, along with the work of another prominent researcher in the area (Leslie Rescorla), laid the foundation for the development of the CDIs (Fenson et al. 2007). The CDI is an example of a measure that relies exclusively on parent report. It has endured the

test of rigorous scientific scrutiny, and there is now tremendous evidence in support of its reliability and validity. As a parent-informant measure, the CDI is especially important as parent-reports can provide a more representative sample of language than may be obtained in clinical settings where spontaneous speech or test results may be influenced by characteristics of the child (e.g., shyness) or testing situation (e.g., familiarity with the examiner) (Fenson et al.). For all of these reasons, the CDI has become a well-respected measure, which continues to lend support to the notion that parents are valuable, reliable, and accurate sources of information. It has been particularly welcomed from a family-centered perspective (e.g., Westby 1998) where parents and other caregivers are recognized as valuable partners in the assessment process.

Psychometric Data

The *CDI: Words and Gestures* is normed on a sample of 1,089, and the *CDI: Words and Sentences* is normed on a sample of 1,461 with a relatively even distribution of girls and boys across the age ranges sampled. Although these 2007 expanded norms more closely approximate national demographic statistics than the original 2,000 norms, the developers note that the sample still underrepresents children and families with low educational and/or socioeconomic backgrounds. In addition, Caucasians are slightly overrepresented, whereas Hispanics are underestimated (a likely result of exclusion criteria requiring children to be from a home where English was the primary language). Normative data for birth order and exposure to a second language are comparable to the US census statistics.

Two types of reliability of the CDIs are well documented. Internal consistency, or the degree to which items on a test measure the same content domain, indicates a very high degree of consistency. The test-retest reliability over an approximate 1–2-month interval is also high indicating excellent stability over time.

The validity of the CDIs is similarly well established. First, the CDIs demonstrate good

content validity, which is the degree to which the test covers the intended content domain. Indeed, the content of the CDIs was developed in line with the language development literature, is supported by over 30 years of child language research, and has been credited as adequately sampling early vocabulary and grammar development (e.g., Westby 1998). Concurrent validity, based on the relationship between CDI scores and various child performance measures, is particularly impressive. Moderate to high correlations have been reported across numerous studies on typically developing children as well as children with language impairment and developmental delays. For example, sections of the CDI are significantly correlated with standardized tests like the *Bayley Expressive Language Scales*, the *Peabody Picture Vocabulary Test*, and the *Expressive One-Word Vocabulary Test* as well as language sample measures like the *Index of Productive Syntax* (Scarborough 1990) and Number of Different Words (NDW).

Clinical Uses

The CDIs were normed on a sample of young typically developing children, and they are not intended to screen for, or identify children with, autism spectrum disorder (ASD). On the other hand, the evaluation of language is important in the assessment of young children with ASD who often demonstrate qualitative impairments in language as well as language delay. In this light, the CDIs have gained utility as a clinical tool in ASD when supplemented by direct measures of child performance, and evidence of the accuracy of the CDIs for screening (Filipek et al. 1999) and diagnosing ASD (e.g., Luyster et al. 2007) is accumulating.

The inventories are well suited as one component of a broader screening procedure (Klee et al. 1998) for language delay, which typically includes the criterion that a child of 24 months uses fewer than 50 words. Experience suggests that this criterion is commonly applied to young children at risk for ASD through use of the CDIs. In a related vein, research shows that deficits in both receptive and expressive language are more

predictive of language impairment than expressive language deficits alone (e.g., Thal et al. 1991). Because the inventories tap both receptive and expressive vocabulary, they can facilitate this analysis with the understanding that no single measure should ever be used as a basis for identification or assessment (Fenson et al. 2007). The use of the CDIs as an evaluation and assessment tool is reinforced by the finding that it has been found to discriminate children with language impairment from those who are developing typical language (Skarakis-Doyle et al. 2009).

Charman et al. (2003) systematically examined the language profiles of preschoolers diagnosed with ASD using the CDIs. Despite considerable variability, children with ASD demonstrated the expected receptive and expressive language deficits described above. Compared to the typical pattern, however, the word production of children with ASD was relatively in advance of word comprehension. With regard to gestures, later developing gestures (pretending to be a parent) were relatively in advance of early developing gestures (e.g., reaching, pointing), which involve joint reference and direct social interaction. Studies such as these are important because they demonstrate how the CDI can be useful in clinical work with young children with ASD (Charman et al. 2003).

Fenson et al. (2007) report that the CDIs are useful for documenting the language abilities of older children representing special populations, including ASD, and they have become increasingly popular for that purpose. Of course, successful implementation of the inventories to assess the language development in children with ASD requires that the scores obtained never exceed the developmental level tapped by the CDI (i.e., 30 months). The developers of the CDI are clear that when scores of older children from special populations exceed this level, serious misjudgments of communicative skills can occur due to ceiling effects.

The CDIs have also been used in the development of intervention strategies. Fenson et al. (2007) suggested that the measure be used to identify overall receptive vocabulary deficits but not to identify specific words that are or are not understood for remediation. They further note that

the case may be different for productive vocabulary where specific words are unambiguously present or absent. “Clinicians may wish to use the CDIs to identify classes of words that appear to require remediation and supplement these findings with more targeted behavioral assessments of individual words” (p. 44).

In summary, the CDIs have proven to be clinically useful for assessment of language deficits, which represents a major characteristic of ASD. When combined with direct measures of child performance, it can be used to screen and evaluate the presence of a language deficit. It can also be used to document the language abilities of children with ASD and guide intervention efforts. As noted above, the CDIs may be particularly attractive because, unlike formal child performance tests, they are not influenced by child situational or motivational factors. Instead, they rely on parent knowledge that has accumulated over time during which the parent has had the opportunity to observe and form impressions about the child’s skills.

Of course, each clinical application raises questions to consider when determining the appropriateness of the measure and interpretation of scores. In particular, use of the CDI norms with children whose developmental age exceeds the upper limit of the inventories is not recommended. It is also prudent to recall that percentile data for some sections of the CDI are unstable, and so interpretation of all percentile data requires care.

Macedonia and Autism

Vladimir Trajkovski
Macedonian Scientific Society for Autism,
Institute of Special Education and Rehabilitation,
Faculty of Philosophy, Ss. Cyril and Methodius
University, Skopje, Republic of Macedonia

Historical Background

The Republic of Macedonia has gone through a long and painful process of transition during last 25 years. The cumulative effect of the transitional recession and the socially stressful process of transition have most seriously affected marginalized groups, such as persons with autism spectrum disorders being among the most vulnerable (Trajkovski 2008).

Autism in Macedonia has a short history. It is not like the history of autism in the USA or other western developed countries. For many decades, especially during the communist period of Yugoslavia, children with autism were diagnosed as mentally retarded, schizophrenic, or some other diagnosis. Children and adults with autism missed regular treatment because of inadequate institutions, lack of finances, parental ignorance, and prejudices in the society. Many of the children with autism have been placed into big institutions such as the Special Institute in Demir Kapija. Because of the poor economic situation, low standard and inappropriate services of social assistance; families were no longer able to care for the medical, physical, and psychological needs of their children and found institutions to be some alternative. Macedonia also has a history

of reporting fewer cases of ASD than can reasonably be assumed to exist nationally, indicating the probable existence of cultural biases or other errors in diagnosis (Trajkovski et al. 2005). So, there are no reliable data about the statistics on how many children with ASD are diagnosed. A National Register of persons with ASD is not established yet.

The first case study about child with autism was described more than three decades ago (Kopachev and Nastov 1983). Then, after 13 years without any activities from the governmental or nongovernmental sector, the first parent association was established in 1996. The Society started its activities and was very productive for 2 years. Children were included for treatment in special schools and institutions for rehabilitation in Skopje. Due to a lack of interest, the society stopped its activities in 1998 (Ajdinski 2005). The author of this entry started with the first doctoral thesis about autism entitled: “Immunogenetic analyses in persons with autism in Republic of Macedonia” in November 1999. Following the research and treatment of autism in the world, the Institute for Special Education and Rehabilitation at the Faculty of Philosophy and the Institute for Immunobiology and Human Genetics at the Faculty of Medicine took the initiative and the Macedonian Scientific Society for Autism (MSSA) was established as an NGO in May 2000. MSSA directed its work towards: primary prevention of people with autism, research on the mechanisms referring to autism, research on the effects of rehabilitation of people with autism, treatment of people with autism, as well as coordination with both governmental and nongovernmental organizations and cooperation with international organizations dealing with autism. In a very short time, the NGO established the number and presented a survey of families with autistic people and started to prepare the National register, introduced two web sites on the Internet (Autism-Macedonia and a web site of the association), became a member organization of Autism Europe, and published a brochure about people with autism. Its members started to participate in scientific projects, attending at conferences in the country and abroad, and had

presentations on TV and radio broadcasting. Their professional and scientific works were published in scientific journals.

There is a lack of knowledge on ASD among professionals who are involved in work with children with ASD, a lack of standardized protocols for early detection, diagnosis, and assessment tools. The precarious use of international classifications and diagnostic tools are resulting in low and late detection of autism. Officially in Macedonia, the ICD-10 diagnostic manual is still used in the health care system (ICD, 1992).

In spite of our lobbying activities during last 17 years, there is still no national strategy about autism spectrum disorders in the country.

Legal Issues, Mandates for Service

Article 39 from the Constitution of the Macedonia guarantees that every citizen has the right to health care. Citizens have the right and the duty to protect and promote their own health and the health of others. Article 44 grants the right to education for every citizen. Education is accessible to everyone under equal conditions. Primary education is compulsory and free of charge. According to the Law for elementary education, special educational plans and curriculum are required to nurture and educate pupils with special educational needs.

The Macedonian constitution does guarantee access to health care to its citizens, but local health care providers are not adequately equipped to serve individuals with autism spectrum disorders. Among other issues, there is limited neonatal screening for genetic disorders, the nation lacks a centralized database on disabilities, and the quality of health care in urban centers does not extend to rural areas. Macedonian schools do not have appropriate staff to work with children with autism according the research conducted by the state attorney office in schools in several towns in Macedonia. It showed 93 children with ASD are going to 109 primary schools. The data analyzed by the state attorney office show that only a small number of the schools have a completely professional team which would work with autistic children. Of all 109 schools covered in the survey, only 39% have a professional team comprised of a

teacher, a psychologist, a pedagogue, and a special education teacher. On the other hand, 28% of the schools have no staff whatsoever to work with children with ASD, nor have the parents hired at their own expense a special education teacher who would work with those children (www.independent.mk).

Social institutions on the local level are not capable of ensuring that people with autism can remain in their area of residence and be provided with adequate educational and social services. The lack of statistical data on people with a disability hampers an evaluation of whether all persons with any given disability are socially jeopardized and if they are able to access their rights in the field of social care. The Law on social protection established measures and services in the field of social protection and care through social prevention, de-institutional care, and protection and the right for social support (Trajkovski 2008).

The Republic of Macedonia ratified the UN Convention on the Rights of Persons with Disabilities and its Optional Protocol on 29 December 2011 and it is a step forward in improving the quality of life of people with ASD in Macedonia. The diagnosis of autism or other developmental disabilities does not entitle the individuals or their families to benefits – they have to apply for the disability status.

Overview of Current Treatments and Centers

In the Republic of Macedonia, there is no systematic approach to early intervention services and programs. There are no service providers for the early intervention of children with ASD. Home-based interventions and other social services available in Western Europe and the United States are relatively limited (Trajkovski 2010). Parents access various kinds of treatments for their children, the most popular are training of social skills, psychomotor re-education, biomedical treatment, and treatment with medicaments. Sometimes they use unproven treatments which can be dangerous for the health. The use of ABA and TEACCH is at an incidental level. Macedonian pediatricians,

psychologists, and rehabilitators lack the skills to conduct such early kinds of treatments. There is no effective law in Republic of Macedonia for early intervention practices (Trajkovski and Jurtoski 2016).

According to the Constitution of the Republic of Macedonia, the concept of freedom and rights is embedded in a citizen-liberal democratic concept, which begins with the principle of citizenship. An essential citizenship freedom and right is personal freedom and the right to acquire education, from the elementary to the university level, which ensures not only personal development and the general development of the individual, but also to the ability to contribute to raising the general cultural level of the society in which they live. According to the Law for elementary education, special educational plans and the curriculum are required to nurture and educate pupils with special educational needs. The regional boards of psychology, medicine, and education give recommendations about the conditions which would best serve the child, but the parents are not legally bound to follow them, and they can enroll the child into a school of their choice. Also for education in schools, there is no legislation to guide and support parents into choosing the type of school to send their children to. Great numbers of parents send their children to mainstream schools with a 1:1 specialist assistant who is financed by the parents. Having a child with autism spectrum disorders in Macedonia can have a huge financial impact for the family. It appears that policy makers are not interested in this area and have no understanding of the problems families face who take care of children with autism. Authorities have to start with certificated programs for training the professionals. Almost half of parents are not satisfied with early intervention programs in our country. One third of parents spend between 250 and 350 euros on early treatment which is a significant amount of their own budget (Trajkovski and Jurtoski 2016). Some of children with ASD stay at their homes out of the system of special or general education. There are no statistics on this issue.

In last 2 years, the Ministry of Labor and Social Policy opened two daily care centers for children with ASD in two towns: Skopje and Shtip. In the

last 5 years, three more parental associations were created in Skopje, Shtip, and Bitola, but they have quite low impact in the field due to lack of money and lack of knowledge.

The condition of adult people with ASD is very bad. Nobody takes care of them. They do not have access to complementary treatment approaches. Many individuals with ASD who do not receive enough support from their families, especially adults, are institutionalized into neuropsychiatric institutions.

Overview of Research Directions

The first publication about autism from Macedonia in a scientific impact factor journal appeared in 2004 (Trajkovski et al. 2004). Two scientific and clinical handbooks such as *Autism* (Trajkovski 2004) and *Autism and Pervasive Developmental Disorders* (Trajkovski 2011) and some articles are published in Macedonian language and because of that not readily available for international audience (<http://www.mssa.org.mk>). Also, there are a significant number of publications in international peer-reviewed journals, such as those dedicated to the plasma concentration of food-specific antibodies in children with autism (Trajkovski et al. 2008), family analysis of immunoglobulin classes and subclasses in children with autism (Spiroski et al. 2009), and immunogenetics and autism (Trajkovski and Spiroski 2015). Some other research groups have published more socially oriented research, such as sexual development, sexual behavior and gender identity of persons with autism (Mladenovska and Trajkovski 2010), employment of people with autism (Stankova and Trajkovski 2010), stress, coping and support among parents of children with autism (Nolcheva and Trajkovski 2015).

Overview of Training

Only physicians (psychiatrists and pediatricians) are allowed to diagnose autism officially. A wider range of specialists provide educational and rehabilitation services. On the initiative of the writer

of this article, the Institute of Special Education and Rehabilitation at the Faculty of Philosophy introduced the subject of Autism into the curriculum of postgraduate studies in 2004 and the subject of Pervasive Developmental Disorders into the curriculum of doctoral studies in 2012 (<http://www.fzf.ukim.edu.mk>). Twelve graduation theses, six master theses, and two doctoral dissertations were defended with autism as a main topic in last 15 years. Our University “Ss. Cyril and Methodius” trains specialists in special education and rehabilitation and speech pathologists (<http://www.ukim.edu.mk>).

The Macedonian Scientific Society for Autism provides free lectures about autism and specific approaches, such as PECS, TEACCH, and ReAttach method. The organization also participated in an EU-funded project regarding parent and professional education in conjunction with the Apollonia Foundation from Gevgelija. However, the majority of events are on an ad hoc basis and are inaccessible to most families (ESIPP project, 2015). Though parent education programs exist in parts of Europe, in others they are extremely limited or nonexistent. In 2015 the Macedonian Scientific Society for Autism started as a partner in a 3-year project (September 2015–August 2018), funded by the European Commission, in which family members, professionals, and academics from five European countries are working together in a strategic partnership to address this inequity (Belgium, Croatia, Cyprus, Macedonia, and UK). This partnership is seeking to develop a core curriculum and ecologically valid parent education materials and methods, provide parent education to families living with autism in three south-eastern European countries where previously it has been unavailable, evaluate impact using quantitative and qualitative methods, share the curriculum and materials with stakeholders, and make recommendations to decision makers (Preece et al. 2016).

Social Policy and Current Controversies

Our society is not sensitized to those persons with autism spectrum disorders. They are looked down

upon, bullied, and regarded as less valuable than children with typical development. Parents hide their children with autism and do not want to expose them in public. They are ashamed of their own children and are not very eager for them to appear in electronic media. There is a huge social stigma connected to having a person with an ASD diagnosis in the family. The authorities are not interested in helping these families. The governmental bodies do not allocate enough financial resources to this sector. In last 6 years, there have been significant changes in public awareness of autism and in social policy since MSSA started to honor international autism awareness day.

Areas of controversy focus on the role of no established treatments (especially ABA and TEACCH), in best approaches to teaching and service delivery, and issues of diagnostic practice. There is a tremendous dearth of work on adults with ASD. The authorities need to begin to see this disorder as treatable and to invest the same energy, money, and efforts into treating autism that we have put into treating cystic fibrosis, leukemia, childhood cancers, and other chronic medical disorders that affect young children.

Macrocephaly Phenotype and Psychiatric Comorbidity in Autism Spectrum Disorder

Lilia Albores Gallo¹ and Fred R. Volkmar²

¹Research in Genetic, Clinical and Community Epidemiology, Hospital Psiquiátrico Infantil Dr. Juan N. Navarro, México City, Mexico

²Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

Macrocephaly is defined as a measurement of the head circumference which is 2 standard deviations (SDs) larger than the mean for a given age and sex (Bray et al. 1969). It is also known as occipitofrontal circumference (OFC), and it denotes the size of the cranium. It is different from megalencephaly, which is defined as increase in the size of the brain parenchyma exceeding twice the standard deviation (Fletcher 1900). Megalencephaly and macrocephaly may coexist in the same individual (Gooskens et al. 1988).

Macrocephaly can be idiopathic, familial, and benign. However, it can be the first indication of autism. In contrast megalencephaly is more often syndromic (Tan et al. 2018).

Evidence shows that the head size correlates with the whole brain volume and weight (Aylward et al. 2002), but it is not caused by hydrocephalus (Filipek et al. 1992; Piven et al. 1995).

The head circumference is a useful index of brain size in children, and it is measured along the most prominent diameter of the occiput and the mid forehead.

Historical Background

The presence of macrocephaly, in some children with autism spectrum disorder (ASD), is a phenotypic characteristic described by Leo Kanner in 1943 (Kanner 1943).

Current Knowledge

Macrocephaly affects children with ASD in a range from 15% to 35% compared to 3–5% in the general population without autism (Courchesne et al. 2001; Aylward et al. 2002; Dementieva et al. 2005; Sacco et al. 2007; Dissanayake et al. 2006; Sacco et al. 2007, 2010), and it is the most common physical sign seen in ASD (Courchesne et al. 2003).

The fact that macrocephaly affects only a subset of children is probably the reason why it is not included as a diagnostic criterion for autism in the DSM-5 or ICD classifications.

Interestingly macrocephaly is absent at birth among some individuals with autism (Dissanayake et al. 2006; Sacco et al. 2010; Gray et al. 2012), which is the result of a higher growth rate of the brain during the first year of life (Froehlich et al. 2013; Constantino et al. 2010; Courchesne et al. 2003), predating the diagnosis of autism (Dawson et al. 2007).

Some studies show that macrocephaly is transitory because after 2 years the growth of the head circumference stops and some children with autism will no longer meet the criteria parameters for macrocephaly (Aylward et al. 2002; Courchesne et al. 2001). However recent evidence shows that there is a subgroup of boys with autism who have brain enlargement persisting until 5 years of age (Libero et al. 2016).

Several studies have proven macrocephaly is familial and heritable. First-degree relatives of children with macrocephaly have larger head sizes compared to first-degree relatives of individuals without autism (Sacco et al. 2007, 2010; Constantino et al. 2010).

Interestingly, macrocephaly in children with autism is apparently not present in all regions of the world such as Sweden, Israel, and Denmark

(Cederlund et al. 2014; Davidovitch et al. 2011; Aagaard et al. 2018), and studies performed with representative samples from the general population have shown the absence of this feature in individuals with autism (Barnard-Brak et al. 2011; Sacco et al. 2015).

Moreover, differences of fetal head growth between the Netherlands and Australia in a recent study show that the Dutch group had a lower initial prenatal head circumference associated with later autistic traits but not the Australian group, suggesting a role for environmental factors (Blanken et al. 2018).

Some recognized triggers affecting the fetal brain growth are the maternal thyroid dysfunction and vitamin D deficiency, which could also lead to autism-like symptoms (Whitehouse et al. 2013; Korevaar et al. 2016; Vinkhuyzen et al. 2018).

In the same lines, a recent study showed that valproic acid-exposed children during the first trimester of pregnancy compared to the unexposed children had a large cephalic index. The large cephalic index was present in valproic acid-exposed children both with and without ASD (Stadelmaier et al. 2017).

The association between macrocephaly and autism severity has been studied with mixed results. Lainhart et al. (1997) demonstrated a small negative correlation between macrocephaly and core symptoms measured through Autism Diagnostic Interview-Revised (ADI-R) but found no association between macrocephaly and head circumference percentile with nonverbal IQ, verbal status, seizure disorder, neurological soft signs, or other minor physical anomalies in individuals with autism.

Fidler et al. (2000) found that macrocephaly was associated with higher scores on the stereotyped behavior domain of the ADI-R. Later on, Lainhart et al. (2006) show an association between social deficits measured through ADI-R and delayed language and macrocephaly in a large collaborative study. Davis et al. (2013) reported an association between higher head circumference and social deficits measured through ADI-R in individuals classified as simplex but not in individuals classified as multiplex. In this study a head overgrowth was identified in 90% of children with

autism from both simplex and multiplex families with a nonverbal IQ < 70 and a nonverbal IQ > 100, respectively, suggesting the importance to include the type of family as a variable with an interaction effect (Davis et al. 2013).

In contrast, a recent study by Webb et al. (2007) found no association between head circumference and signs of language or social regression in children with autism despite using the same definition from the Autism Diagnostic Interview-Revised.

There are less studies between the association of macrocephaly in children with ASD and psychiatric comorbidity. Miles et al. (2005) reported that families of probands with autism and macrocephaly had a significantly lower likelihood of having a family history of ADHD compared with the normocephalic group. In the same lines, Aagaard et al. (2018) through a register-based cohort study of all Danish singletons found that macrocephaly was associated with a decreased risk of ADHD (HR 0.90, 95% CI 0.82, 0.99), but neither microcephaly nor macrocephaly was associated with ASD (HR 1.06; 95% CI 0.94, 1.19, and 1.03; 95% CI 0.90, 1.19).

In a clinical setting, Albores-Gallo et al. (2017) demonstrated that 20% of Mexican children with autism had macrocephaly. The frequency of psychiatric comorbidity was very similar in the groups with macrocephaly (78.4%) and without macrocephaly (79%). The most associated comorbidity in the group with autism and macrocephaly was attention deficit hyperactivity disorder (ADHD) with 46%, followed by specific phobia with 16% and separation anxiety with 6.4%.

Future Directions

Macrocephaly should be more studied because evidence shows that stratifying by head circumference increases the power to detect differences in genetic studies as suggested by Conciatori et al. (2004).

More research is necessary with larger sample size and longitudinal studies. Since cephalic growth patterns associated with autism vary in different countries, it is important to investigate

some prenatal environmental factors such as diet, use of vitamins and regional teratogens, maternal exposure to stress, viral or bacterial infection, and thalidomide and valproic acid use as triggers for cerebral overgrowth (Grabrucker 2013). Since macrocephaly precedes the emergence of symptoms of autism, it would be interesting to focus on risk factors postnatally like fever, viral or bacterial infections, and nutritional deficiencies, which could trigger cephalic overgrowth.

The inclusion of the cephalic type as a specifier in the diagnostic classifications of DSM or ICD would be important for detecting associations in prospective and retrospective studies of autism.

Macrographia

Giacomo Vivanti

A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, USA

Definition

Macrographia is abnormally large handwriting. It might be seen in patients with cerebellar disease (Haymaker 1956) and basal ganglia dysfunctions such as Huntington disease (Phillips et al. 1994). It has also been observed in a sample of patients with aphasia (Fradis and Leischner 1985). Macrographia has been documented in both children and adults with autism spectrum disorder (Beversdorf et al. 2001; Johnson et al. 2013). In the Johnson et al. study, macrographia was associated with poor manual dexterity. Overall, these findings might reflect abnormalities in the prefrontal/basal ganglia/cerebellar motor network in the ASD population. However, more empirical research is needed to investigate the nature of handwriting abnormalities in autism.

Magnetic Resonance Imaging

Natasa Mateljevic¹ and Roger J. Jou²

¹Yale University, New Haven, CT, USA

²Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Definition

Magnetic resonance imaging (MRI) is a noninvasive technique by which detailed images of internal anatomy are constructed by measuring the response of atomic nuclei to strong magnetic fields and innocuous radio waves. The hydrogen proton (1H) is the atomic nuclei of choice due to its abundance in water molecules which makes up most of the human body's mass. During the procedure, protons emit unique signals which depend on their distinct chemical environment. These signals are then used to construct a series of two-dimensional images, which taken together, can provide valuable information of soft tissue (i.e., organ, muscle, etc.) anatomy in three dimensions. MRI uses no ionizing radiation and is well known for being a painless and harmless procedure. This

is evidenced by its widespread use in the clinical and research arenas in populations spanning the entire age range from infants to the elderly. In clinical practice, MRI is best known as a diagnostic tool used to differentiate diseased from normal tissue. However, due to its tremendous versatility and ability to provide accurate, detailed information, MRI has widespread applications in contemporary clinical and research practice.

Historical Background

Nuclear magnetic resonance (NMR) describes the physical phenomenon on which MRI technology is based. The phenomenon of NMR was actually discovered in the 1940s and set the stage for the development of MRI for medical diagnostic use in the 1970s. NMR signals are created by certain atomic nuclei when excited by radio frequency energy in the presence of a strong magnetic field. In 1946, Edward Purcell and Felix Bloch independently developed methods for determining precise nuclear magnetic measurements. This was a monumental achievement, and both were recognized with awards for the Nobel Prize in physics (1952). Spurred by the development of computed tomography in the early 1970s and coupled with advances in the development of new image reconstruction algorithms, chemist Paul Lauterbur and physicist Sir Peter Mansfield created different methods to translate information regarding magnetic spin into cross-sectional images. This seminal work began a rapid progression of continuously improving imaging techniques, and both were jointly awarded the Nobel Prize in physiology or medicine (2003). Many further refinements at various stages have resulted in the acquisition of higher resolution depictions through the improved extraction of signal from tissue over background noise and improvements in the generation of tissue contrast.

Current Knowledge

In this section, a brief review is provided on the physics of MRI as there are now numerous texts

covering this topic in detail (please see References). MRI exploits the magnetic properties of the atomic constituents of biological matter to construct a visual representation of tissue. Specifically in medical MRI, the signal from the nuclei of hydrogen atoms (^1H) is used for image generation since hydrogen constitutes two-thirds of all atoms in the human body. The proton of the hydrogen atom is positively charged and possesses spin, an intrinsic property of all elementary particles. In essence, the proton rotates about its axis and is analogous to a spinning top. The proton, which is found in the nucleus of the hydrogen atom, has considerable mass relative to the electron which orbits around the nucleus. As a rotating mass, the proton possesses angular momentum that strives to retain the spatial orientation of its rotational axis. Since the proton is both charged and in constant motion, it additionally has a magnetic moment and can be imagined to behave as a small magnet. What is basically observed in MRI is the motion of the proton's magnetic axis, which is capable of generating a signal in the MRI scanner's receiver coil.

When an external force acts on the hydrogen proton and tries to alter the orientation of its rotation axis, the proton begins to wobble or precess around its axis of rotation. At the same time, friction caused by the interaction between the external force and the proton withdraws energy from the proton and slows down its rotation. As a result, the proton's axis of rotation becomes progressively more inclined and if imagined as a spinning top, finally falls over. More specifically, when hydrogen nuclei are exposed to an external magnetic field, the magnetic moments (or spins) align with the direction of the field and simultaneously undergo precession. The precession of the nuclei occurs at a characteristic speed that is proportional to the strength of the applied magnetic field and is called the Larmor frequency. The Larmor frequency is the rate at which spins wobble when placed in a magnetic field. The spin system eventually relaxes and settles into a stable state, but the longitudinal magnetization (M_z) builds up in the z-direction because the magnetic vectors representing the individual magnetic moments accumulate. The spins tend to

align parallel and antiparallel to the magnetic field, with parallel alignment being slightly more preferred because it is energetically more favorable. Hence, a slightly larger fraction of spins aligns parallel to the main magnetic field. This small difference produces the measurable net magnetization M_z and is represented by the net magnetization vector. This energy difference between the two spin orientations depends on the strength of the external magnetic field with M_z increasing as field strength increases.

Furthermore, energy can be introduced into this spin system by applying an electromagnetic wave of the same frequency as the Larmor frequency, a condition known as the resonance state. This wave is generated in a radio transmitter and applied to the object to be imaged using an antenna coil. The result is that the longitudinal magnetization becomes more and more tipped away from the z -axis toward the transverse xy -plane, which is perpendicular to the direction of the main magnetic field. All of the longitudinal magnetization is rotated into the transverse plane by a radio frequency pulse that is both strong enough and applied long enough to tip the magnetization by exactly 90° . This results in M_{xy} magnetization, which as its name suggests, lies in the xy -plane. Transverse magnetization rotates about the z -axis, which has the effect of an electrical generator and induces an alternating voltage of the same frequency as the Larmor frequency in the MRI scanner's receiver coil. This is called of the magnetic resonance signal which is collected and processed with sensitive receivers and computers to generate the magnetic resonance image.

The magnetic resonance signal rapidly fades due to two independent processes that reduce transverse magnetization and thus return the spin system to the stable state present prior to excitation. These two processes are spin-lattice interaction which causes T_1 relaxation and spin-spin interaction which causes T_2 relaxation. T_1 is defined as the time required for 63% of the original longitudinal magnetization to be recovered. T_2 is defined as the time required for transverse magnetization to decrease to 37% of the original value. T_1 typically ranges from 200 to 2,000 ms and T_2 commonly ranges from 30 to 500 ms. T_2

denotes the process of energy transfer between spins, while T_1 refers to the effects of additional field inhomogeneities contributing to spins losing coherence. A key strategy for how differences in T_1 and T_2 are exploited to generate tissue contrast involves strategic variation of timing and orientation of repetitive radio frequency pulse delivery.

MRI's ability to localize signals in the three-dimensional space of the brain is accomplished by using magnetic gradients which are magnetic fields which change gradually along an axis. Encoding of a three-dimensional volume begins by first dividing the tissue mass into slices. Then two distinct magnetic gradients orthogonal to each other are applied, effectively dividing each slice into rows and columns of pixels. By doing this, each pixel possesses unique precessional frequency and direction. A special mathematical operation, called Fourier transform, converts pixel data back into three-dimensional voxels, which are then assembled to form an image volume reconstruction of the original three-dimensional tissue mass. Optimal spatial resolution currently approximates 1 mm^3 or less.

Proton densities and differential T_1 and T_2 relaxation effects are properties intrinsic to brain tissues, and subsequently, their measurement forms the basis for the provision of differential tissue image contrast in MRI. Different tissue parameters can be differentially weighted, thus, yielding a variety of image types, each providing a unique range of diagnostic information. Different image modalities are usually identified by numeric values of key pulse sequence parameters set during acquisition. Use of shorter repetition time between pulse sequences during image acquisition interrogates tissues at a moment when their intrinsic T_1 differences can be exploited to yield different signal intensity production and hence tissue contrast generation. The resulting image, whose contrast is based on tissue differences in T_1 , is termed T_1 -weighted. A repetition time less than 500 ms is considered short; a repetition time greater than 1,500 ms is considered long. Use of repetitive 90° pulses to detect T_1 -based tissue contrast is called a saturation recovery sequence. Alternatively, inversion recovery involves a sequence that begins with a

180° pulse followed by a 90° pulse. The 180° pulse reverses longitudinal magnetization, and all protons responsible for the net magnetic moment are inverted 180° in the applied longitudinal magnetic field. The signal that is received depends on the time between the 180- and 90° interrogation pulses, which constitutes the repetition time for this particular pulse sequence. On the other hand, a primary strategy for generating T2-weighted images involves use of a pulse sequence termed spin echo. In spin echo, an initial 90° pulse generates transverse magnetization vector component. When 90° pulse is terminated, dephasing follows under the influence of T2. When 180° pulse is administered, the direction of dephasing protons is reversed. More slowly, precessing protons are now ahead of faster ones. Eventually, protons with faster precession frequencies catch up, culminating in proton precession rephrasing and thus detectable signal generation. This process is repeated, and protons again dephase, are again refocused by another 180° pulse, and so on. Therefore, it is possible to obtain more than one signal by repeating the spin-echo sequence.

In clinical practice, substances with short T1 producing high signals on T1-weighted imaging include fat, methemoglobin in subacute hemorrhage, and paramagnetic contrast agents. Substances with long T1 producing low signals on T1-weighted imaging include cerebral spinal fluid and tissues in which any process that increases local water has occurred (i.e., inflammation). T1 images are best for visualizing normal anatomy. Tissues with longer T2 generate higher signals on T2-weighted images. Because of the greater fluid content of a tissue, the longer the tissue's T2, the brighter that tissue's appearance on a T2-weighted image. Thus, T2-weighted images highlight fluid-containing regions, such as sulci and ventricular system. Also in a healthy brain, T2 constitutes the entirety of high intensity signal. Substances with short T2 produce low signals on T2-weighted images. Examples include iron-containing substances. Also, most brain lesions involve associated change in water content, such as cellular injury (infarction) and extracellular inflammatory lesions (mass lesions) which produce vasogenic

edema. Because a final common pathway of many brain lesions involves increases in water content of brain, T2-weighted images, which highlight tissue with higher water content, demonstrate brain pathology as higher signal intensities. T2-weighted images are useful for evaluating sulcal widening in cortical atrophic syndromes and for evaluating hydrocephalus.

Future Directions

In the decades to come, advances in MRI technology include a widespread transition to higher magnetic field imaging, enhanced MRI coil sophistication incorporating even more channels, ultrashort echo-time imaging, tighter integration of multiple imaging modalities, and advances in molecular MRI agents. Currently, the typically used clinical imaging scanners operate at 1.5 T. While systems operating at even higher field strengths have become more prevalent, they are found mainly at major medical centers. Current clinical interest focuses on transitioning to 3 T scanners; however, it is already evident that much higher field strengths will eventually be used to examine patients (up to 7 T, which so far have only been used in research studies). Available data suggests that magnetic field strengths above 2 T involve no increased risk for patients, but the strongest argument for increasing field strength is the expectation that this will significantly boost signal-to-noise ratio. Improved signal-to-noise ratio leads to increased spatial resolution and/or reduced imaging time. An improved spatial resolution permits better anatomical evaluation. Shorter scan time leads to better tolerability and more cost-effective operation (more patients can be examined per unit time). Finally, imaging at 3 T or higher field strengths has the potential to improve more sophisticated applications of MRI such as functional imaging and carbon-13 or hydrogen-1 spectroscopy. For example, it is known that the chemical shift increases in proportion to magnetic field strength and the larger chemical shift is advantageous in spectroscopy because the spectral lines spread farther apart. Thus, this improves

spectral resolution and discrimination of the peaks of fat and water, which in turn enables better calibration of the radio frequency pulse for fat suppression, which can significantly diminish the peaks of interest. Also, increasingly higher numbers of radio frequency channels will become standard, having a significant impact in neurological examinations. Commercial products for simultaneous acquisitions of both positron emission tomography and MRI will become commonplace in many centers where their use will be justified by improved throughput, improved patient compliance, and improved image and diagnostic accuracy. Of key importance in combined modalities, however, is the validation of image quality acquired by one modality in the presence of the other. For example, the verification that positron emission tomography image quality is not impaired by placing the detector system into the magnetic field and that MRI quality is not degraded by the presence of the positron emission tomography detectors. In addition to multimodal imaging, the future will also bring a wider application of current methods into other body areas (such as the use of diffusion tensor imaging in non-neurological examinations). Finally, the development of targeted contrast media is a rapidly expanding area in MRI research and is already being frequently used in animal systems. These contrast agents show areas of abnormality in terms of passive accumulation of agent within the tissue, for example, a normal brain will exclude contrast from the parenchyma, but damaged tissue allows passive diffusion of contrast agent through the compromised blood-brain barrier, leading to image enhancement. The future will also bring very highly sensitivity agents that either are targeted to specific disease processes or provide specific information on regional metabolism.

Definition

Magnetic resonance spectroscopy (MRS) is a technique similar to magnetic resonance imaging (MRI) that can extract chemical information about biological tissues. MRS is also known as nuclear magnetic resonance (NMR) spectroscopy, though this term tends to be avoided in in vivo work. MRS can be accomplished in most clinical MRI scanners and is similarly safe. However, rather than providing an image of the tissue as MRI would, MRS provides a “spectrum,” or chemical signature, of the area under examination. From this, metabolic and biochemical disturbances can be identified in a region-specific fashion. MRS has applications across the body; however, one of the most prominent applications of MRS is to examine biochemical disturbances in the brain.

Historical Background

For a brief history of NMR, please see ► [“Magnetic Resonance Imaging”](#).

Early work in the 1970s showed that MRS could be used to obtain chemical information from living animal tissue, such as blood cells or muscle tissue (de Graaf 2008). However, it was not until the early 1980s that the brain was examined under ^1H MRS in living mammals and humans (Ross and Bluml 2001). These studies paved the way for neurospectroscopic applications, ranging from the evaluation of traumatic brain injuries to predictive markers of Alzheimer’s disease risk to studies of neuropsychiatric disorders such as schizophrenia and autism.

Current Knowledge

Utility and Applicability of MRS

As MRS can typically be conducted with the same equipment as standard MRI, MRS can be considered a very accessible and well-tolerated radiological imaging modality (for comparisons with other modalities, see Siegel and Albers 2006). As with MRI, MRS uses nonionizing radiofrequency pulses for excitation of nuclei and magnetic field gradients for spatial localization. MRS does require, however, specifically built pulse sequences for acquiring data and specialized algorithms and frameworks for analysis. These modifications and additions are widely available on most clinical MR machines.

However, it is also important to note that MRS encompasses a wide range of both clinical and research endeavors. Many types of specialized sequences exist (e.g., see section [“MRS of GABA in Autism,”](#) below) as do specialized protocols (some of which look at other nuclei besides ^1H that are MR-detectable, e.g., ^{31}P , ^{13}C). The bulk of this article will discuss applications that are most relevant to studies of autism, primarily in vivo ^1H MRS of the human brain.

Differences Between MRI and MRS

In standard MRI, pulse sequences are chosen to emphasize specifics regarding the spatial

distribution of protons, resulting in an image. Thus, the strongest contributors to an MRI profile are water and fats. By contrast, MRS seeks to optimize the provision of spectral information, specifically isolating metabolites and other biochemicals in an organism. Because different nuclei on a molecule may exist in distinct chemical environments, and because each of these chemical environments can result in different levels of “shielding” from the external magnetic field of the MRI machine, this results in certain molecules having “chemical signatures” that are different from other molecules (see section [“ \$^1\text{H}\$ MR Spectra in the Human Brain”](#)). However, the concentrations of these chemicals are often very low, and thus the signal from metabolites, e.g., in the brain, is approximately 10,000 times smaller than that of water. For this reason, additional steps are typically taken both at the time of spectral acquisition and data processing for eliminating dominating signals from water or fats so that other metabolites will be visible (de Graaf 2008; Shic et al. 2010).

^1H MR Spectra in the Human Brain

The most common form of MRS in use today for studying in vivo brain biochemistry is ^1H MRS. This form of MRS uses the same type of head coils as MRI and can typically be conducted as part of a standard clinical imaging examination. A typical MR spectrum is shown below.

MR spectra are typically displayed with frequency (chemical shift) on the x-axis, expressed in parts-per-million (PPM). PPM is the frequency

difference between a reference chemical (typically tetramethylsilane) and a particular frequency, all divided by the frequency of the MRI machine and multiplied by a million. Since the frequency of the MRI machine scales linearly with its field strength, PPM provides a field-independent axis of chemical shifts for metabolites. The y-axis of MR spectra is the signal intensity, a value that scales with the concentration of a metabolite.

A detailed discussion of the clinical utility and biochemical processes underlying MRS-detectable metabolites is beyond the scope of this article (for more details, please see Ross and Bluml (2001) and Lin et al. (2005)), as are the optimizations necessary for obtaining high-quality spectra (for practical advice and theoretical considerations, see Blüml 2011). Briefly, however, primary metabolites seen in *in vivo* 1H MRS of the brain include: (1) lipids, typically seen in voxels containing subcutaneous fats from the skull or in necrotic tissue; (2) lactate, which appears as a doublet at 1.33 PPM, a by-product of anaerobic glycolysis which is naturally occurring at low concentration levels in the cerebrospinal fluid but which can also be seen in hypoxia and stroke; (3) N-acetyl aspartate (NAA), a marker for healthy neurons, axons, and dendrites, which is decreased in events such as hypoxic or traumatic brain injury; (4) the glutamine and glutamate complex (Glx), which includes both glutamine and glutamate due to overlapping chemical profiles, is involved in inhibitory and excitatory neurotransmission in the human brain and is disturbed in some neuropsychiatric conditions such as schizophrenia; (5) creatine + phosphocreatine (Cr), energy markers of brain metabolism, which can be disturbed in brain trauma and hyperosmolar conditions such as hyponatremia; (6) choline (Cho), a myelin and membrane marker, elevated in certain tumors and in stroke; and (7) myoinositol, a brain osmolyte and a marker for astrocytes found to be elevated in Alzheimer's disease and diminished in hepatic encephalopathy.

Typically, the levels of metabolites are expressed as either a ratio (e.g., the peak height of NAA divided by the peak height of Cr, i.e., NAA/Cr) or as an absolute concentration level

(typically enclosed in brackets, e.g., [NAA]). Creatine is often used as a reference signal for studies reporting ratios, given its relative homeostatic stability. However, it is important to note that creatine concentrations can be affected by some pathologies (see Ross and Bluml 2001 for details). Several methods exist for quantifying absolute concentration levels of metabolites, but the analysis is more complex and often involves assumptions regarding the spectral shape of metabolites, the creation of model solutions for use as a basis set, and the use of brain water as a reference (Christiansen et al. 1993; Kreis et al. 1993; Pouillet et al. 2008).

Single-Voxel and Multivoxel Spectroscopy

As in MRI, there exist many different protocols for acquiring MRS from the brain. Typical 1H clinical examinations can be broken down into single-voxel techniques and multivoxel techniques. In single-voxel spectroscopy, a small area in the brain is chosen *a priori*, based on scout images or prior MRI in the same session as the MRS session, and 1H MR spectra acquired from those locations. In multivoxel spectroscopy (also called spectroscopic imaging or chemical shift imaging), spectra are obtained from a wide area under additional phase encoding, thus providing chemical profiles from multiple locations within a larger spatial volume. The advantages of multivoxel techniques include increased ability to detect atypical neurochemical profiles over a larger space and greater time efficiency of detection over the volume compared to comparable serial single-voxel MRS. The disadvantages of multivoxel techniques are increased complexities in data analysis, increased difficulties in controlling for magnetic field inhomogeneities (due to the larger size of the whole volume), and “voxel bleeding” (i.e., contamination of chemical profiles within one voxel with spatially adjacent voxels) (see de Graaf 2008 for details).

Short- and Long-Echo Spectroscopy

The appearance of 1H MR spectra is highly dependent on parameters of the pulse sequence employed. The width of peaks in MRS is partially determined by T2* time, a property of a molecule that includes both T2, the transverse relaxation

time of a metabolite, as well as magnetic field inhomogeneity effects. Less mobile molecules, such as lipids, tend to have lower T2 times (and hence lower T2* times), effectively translating into peaks that are broader and shorter. The echo time of an MRS pulse sequence (the TE time) will refocus (i.e., help to eliminate) inhomogeneity effects, but not T2 effects, with the resultant effect that longer TEs result in decreased visibility of short T2 time metabolites. This has advantages as well as disadvantages. The disadvantages include the decreased visibility of important metabolites with shorter TEs which become harder to identify at longer TEs and the generally decreased signal-to-noise (SNR) ratio associated with waiting for metabolite signals to decay. The advantages include less complex baselines, i.e., less contamination by “nuisance” molecules which alter the shape underlying the peaks of metabolites of interest. Some contributors to complex baselines include macromolecules, which have very short TEs (Behar et al. 1994). Typical short-echo times are TE = 30–35 ms, whereas long-echo times range from 135 to 144 ms (lactate, which is a j-coupled resonance, inverts in this range of echo times, making it somewhat easier to detect). Other researchers recommend a midrange TE, e.g., 40–50 ms, as a compromise for relatively flat macromolecular contributions and good SNR (Hetherington et al. 2005).

1H MRS Studies of Autism

Currently, MRS studies have painted a broad picture regarding neurochemical differences between ASD groups and controls, and some researchers have argued, based on low levels of specific neural markers, that autism may be characterized by disruption of neuronal integrity in a region-specific or global pattern (Dager et al. 2008a). The earliest examinations with MRS are of children diagnosed with autism at 3–4 years of age (Friedman et al. 2003).

Region-specific abnormalities in autism reported by 1H MRS studies include decreased NAA in the hippocampus-amygdala (Gabis et al. 2008; Mori et al. 2001; Otsuka et al. 1999), transverse temporal gyrus (Hisaoka et al. 2001), and medial temporal lobe (Endo et al. 2007). Several

groups have also noted functional relationships between NAA concentrations and measures of social functioning (Endo et al. 2007; Hardan et al. 2008; Kleinhans et al. 2009; Oner et al. 2009). It is important to note, however, that several groups have found negative results in similar areas or with different subject populations (Kleinhans et al. 2009; Oner et al. 2009; Perich-Alsina et al. 2002; Zeegers et al. 2007). Nonetheless, abnormal concentrations of metabolites in the temporal lobe, or relationships between temporal lobe and social functioning, are among the most reported results in 1H MRS as applied to the study of ASD. 1H MRS work by some researchers has also identified abnormalities in levels of brain metabolites other than NAA, such as Cho, mI, Cr, and Glx, in a region-specific fashion (e.g., DeVito et al. 2007; Gabis et al. 2008; Hashimoto et al. 1997; Kahne et al. 2002; Levitt et al. 2003; Mori et al. 2001; Murphy et al. 2002; Sokol et al. 2002; Vasconcelos et al. 2008), though the results are somewhat varied, possibly due to differences in subject populations, acquisition parameters, and experimental protocols.

Some groups have also reported what appears to be globally depressed concentrations of all metabolites in autism, primarily as associated with brain gray matter (DeVito et al. 2007; Friedman et al. 2003, 2006; Kleinhans et al. 2007). Friedman et al. (2006), in a particularly relevant study, include as participants the youngest reported group of children with ASD: 45 children 3–4 years of age. Several of these studies, including Friedman et al., also report longer T2 times in autism. T2, also known as spin-spin relaxation time, reflects compartment differences (i.e., where the chemicals are being measured, e.g., intracellularly or extracellularly) and can be interpreted as an indicator of the mobility of the associated metabolite (Dager et al. 2008a). As noted by Dager et al. (2008b), the increased T2 times observed in children with ASD are not compatible with brain overgrowth models of autism which suggest that incomplete neuronal pruning leads to dense neuronal cell packing, as in this case T2 times would be decreased, expressing decreased cellular mobility.

MRS of GABA in Autism

Though standard ¹H MRS protocols can paint a rich picture of neurochemical abnormalities in individuals with ASD, some particularly noteworthy metabolites are difficult to detect using these standard approaches. One such metabolite is GABA, the primary inhibitory neurotransmitter of the central nervous system. GABA exists in low concentrations in the brain, relative to the other metabolites outlined in the section above. Furthermore, the spectrum of GABA is overlapped by other metabolites, obscuring it from view. Recently, Harada et al. (2010) employed a specialized GABA-editing sequence in order to measure GABA levels in the frontal lobe and lenticular nuclei of adults with autism and matched controls. The authors of that study found that adults with autism showed decreased levels of GABA and GABA levels relative to glutamate in the frontal lobe but not the lenticular nuclei, suggesting a frontal lobe-specific disturbance in excitatory-inhibitory neurotransmission.

Mitochondrial Dysfunction in Autism

One application of MRS has been the study of brain mitochondria dysfunction in ASD. Using optimized proton echo-planar spectroscopic imaging, Corrigan et al. (2011) showed no presence of lactate in a longitudinal sample of children with ASD. Since the presence of elevated lactate levels has been suggested to be associated with mitochondrial dysfunction, the finding of no lactate in the study provided evidence against the belief of widespread mitochondrial dysfunction in ASD and, consequently, the practice of hyperbaric oxygen for the treatment of ASD. This study was followed by a healthy exchange of perspectives by researchers on the Corrigan et al. study and proponents of hyperbaric oxygen treatment (Dager et al. 2011; Rossignol and Frye 2011).

Future Directions

Despite some inconsistencies in the literature to date, modern research using ¹H MRS is beginning to reveal rich interactions between brain neurochemistry and cognitive, behavioral, and social

performance in autism. Technological advances, such as more stable spectrometers, increasing field strength, and more reliable and powerful gradients, all contribute to the increased reliability of MRS investigations. Future work will likely replicate and extend prior findings with increasingly specific predictions about the relationships between region-specific neurochemical levels, behavior, and outcome.

The continued application of more advanced MRS techniques, such as GABA and glutamate editing, will deepen our understanding of biochemical abnormalities in autism. As in the example of investigations of mitochondrial dysfunction in ASD, these techniques will augment the tool sets available to researchers for providing evidence against or for new and rising hypotheses about the underlying biological mechanisms of autism. However, given the currently high levels of sophistication necessary to enact some of these protocols and process the results, concerted efforts will be required to delineate the limits of these protocols and to make the techniques more easily available and accessible for translational applications.

A particularly promising application area for MRS research in autism is the use of MRS in tracking the progression and response of individuals with ASD to pharmacological treatment plans. Such strategies have already proven to be useful in other neuropsychiatric disorders (Mason and Krystal 2006). Another area which has been little explored to date is the use of multinuclear MRS for examining nuclei other than proton (¹H), e.g., carbon-13 and phosphorous-31. Multinuclear MRS, especially infusion studies of ¹³C glucose or acetate (e.g., see Bluml et al. 2002), has the potential to provide accurate descriptions of atypical brain metabolism and energetics in autism, potentially identifying points of biochemical vulnerability in a pathway- and individual-specific manner. When combined with genetic studies which may highlight the corresponding bases for these disorders, and the potential of MRS for monitoring and tracking treatment and disease progression, the role of MRS in the study of autism should only increase in the coming years.

Magnetoencephalography

Lauren Cornew and Timothy P. L. Roberts
Radiology Department, Children's Hospital of
Philadelphia, Philadelphia, PA, USA

Definition

Magnetoencephalography (MEG) is a noninvasive neuroimaging technique that detects extracranial magnetic fields produced by electrical activity in the brain, which occurs spontaneously or in response to external stimuli. The extracranial magnetic fields are sampled by an array of sensors, generally arranged in a helmet, within which the head is contained (see Fig. 1). These extracranial magnetic fields, which comprise MEG signals, reflect the synchronous postsynaptic activity of large populations of pyramidal neurons. Electrical activity associated with synaptic transmission produces magnetic fields orthogonal to the direction of the electric currents. The direction of the magnetic fields is governed by the “right-hand rule”: When the right hand is made into a fist with

Magnetoencephalography, Fig. 1 A child sits in a whole-head biomagnetometer (MEG machine). Typically, somatosensory, visual, or auditory stimuli may be presented, and button-box responses collected synchronously with multichannel (in this case 275) recording of the magnetoencephalogram

the thumb pointing upward, the remaining fingers point in the direction of the flow of magnetic fields.

Recording magnetic fields associated with brain activity relies on specialized technology because the magnetic fields in the brain are extremely weak (on the order of 10fT – 1pT , approximately 10 million times smaller than the earth's magnetic field). As such, the coils that detect the brain's magnetic fields and the superconducting quantum interference devices (SQUIDS) to which the coils are coupled are maintained at extremely low temperatures. This is accomplished by surrounding the sensors with liquid helium and encapsulating them within a dewar. In addition, containing the MEG system within a magnetically shielded room reduces competing environmental magnetism.

MEG recording takes place while patients or participants are either seated or lying supine, with the head positioned inside of the helmet that contains the MEG sensors. The size of the helmet is optimal for a typical adult head in the vast majority of MEG systems; however, MEG systems designed for infants and small children are currently being developed. Unlike MRI, MEG recording is silent. Patients or participants may be scanned during rest or during a variety of paradigms, from passive sensory processing to

active task performance, and the signals recorded can be characterized as spontaneous, evoked, or induced. Spontaneous activity is that which is not related to the presentation of a stimulus and thus constitutes background activity. Evoked activity is strictly time-locked to a stimulus, whereas induced activity arises in response to a stimulus but not in a strict time-locked manner.

In order to localize the brain activity recorded at the MEG sensors, the source/s of the activity must be modeled. In so doing, researchers and clinicians are often faced with an inverse problem, that is, the data (in this case, MEG signals recorded outside of the head at the sensors) are used to estimate the model parameters (in this case, the source/s of the MEG signals within the brain). These inverse situations are conceptualized as “problems” because there is no unique solution, and it can be challenging to identify the best possible solution.

MEG source modeling is typically accomplished by combining the MEG signals with MRI images. During MEG data collection, several coils are affixed to the individual's head (usually the nasion and left and right periauricular areas) to establish a three-dimensional coordinate system so that his or her MEG data may be coregistered with his or her structural MRI. The most widely utilized method for MEG source localization is the single equivalent current dipole (ECD) method. This method involves modeling the pattern of MEG activity at relevant sensors with the assumption that the source of the activity is a focal location in the brain (see Fig. 2). An alternative approach to the ECD method is beamforming, which uses rastered spatial filtering to identify the neuromagnetic time course of any given point in the brain. Repeating this process for many points in the brain allows researchers and clinicians to construct images in which the MEG activity of interest is overlaid on the structural MRI.

MEG is related to EEG as the two techniques capitalize on the same neurophysiological processes. However, there are several key distinguishing features of MEG. First, whereas EEG signals are susceptible to distortion due to the skull and scalp, MEG signals are impervious

Magnetoencephalography, Fig. 2 (a) Spatial and temporal information in MEG represented by the spatial array of sensors each recording the time-varying magnetic field; (b) at any instant, the magnetic field topography can be described; (c) source modeling is used to transition for “sensor space” to “brain, or source, space,” in this case,

two equivalent current dipole sources in bilateral superior temporal gyri accounting for auditory evoked neuromagnetic fields; (d) time courses of neuronal electrical activity from the two brain sources illustrated in (c) during auditory stimulation

M

to these structures, thus yielding better spatial resolution in MEG than EEG. Second, whereas EEG detects both tangential and radial currents associated with neural activity, MEG detects only tangential currents. This means that MEG is primarily sensitive to activity in sulci. Third, whereas EEG relies on a reference electrode/s, which can be problematic if the reference is active, MEG is reference-free.

Historical Background

To date, magnetoencephalography has been utilized predominantly for clinical purposes. The most common applications are identifying abnormal patterns of neural activity, locating seizure focus in epilepsy, and preoperative assessment of eloquent cortex in patients with intractable

epilepsy or brain tumors. In the latter, MEG findings have been demonstrated to be superior to EEG findings and consistent with (and perhaps eventually supplanting) invasive methods such as electrocorticography (ECoG).

Current Knowledge

Although MEG is widely considered the “gold standard” for noninvasive characterization of neuropathology in patients with epilepsy and brain tumors and the technique has demonstrated usefulness in the study of disorders such as Parkinson’s disease and schizophrenia, MEG has not been widely applied to the study of autism spectrum disorders (ASD). The earliest MEG studies of ASD were published in the late 1990s, and the relatively small ASD MEG literature can

be divided into the following broadly defined categories: (a) epileptiform abnormalities, (b) mirror neuron system integrity, (c) face processing, (d) the somatosensory system, and (e) auditory/language processing.

Epileptiform Abnormalities

One of the earliest MEG studies of ASD (Lewine et al. 1999) investigated the potential presence of abnormal patterns of neuromagnetic activity during sleep in children with regressive ASD, motivated by the substantial clinical overlap between autism and epilepsy. Results indicated a high prevalence of multifocal epileptiform activity in these children, even in the absence of a diagnosable seizure disorder. Similar epileptiform abnormalities have been subsequently reported in children with nonregressive forms of ASD (Muñoz-Yunta et al. 2008). Importantly, this line of research has demonstrated that epileptiform activity in ASD is detectable with MEG even in cases where it goes undetected by simultaneously recorded EEG.

Mirror Neuron System Integrity

Another small subset of the ASD MEG literature consists of studies examining the integrity of the mirror neuron system. Discovered serendipitously by Rizzolatti and colleagues (Gallese et al. 1996), who observed that neurons in a frontal area in monkeys fired not only when the monkey performed an action itself but also when it observed the experimenter performing a similar action, mirror neurons are purportedly involved in imitation and social cognition. Impairments in the mirror neuron system have been implicated in ASD, mostly with the use of EEG and fMRI. Although an early MEG study investigating electrophysiological signatures of biological motion perception in individuals with ASD (Avikainen et al. 1999) failed to identify abnormalities in ~20 Hz oscillatory activity in primary motor cortex, more recent work has identified spatio- and spectro-temporal abnormalities. Specifically, one finding indicated that although the peak activation latencies between adults with ASD and controls did not differ early in the processing stream (occipital cortex, followed by superior temporal

sulcus, followed by inferior parietal lobule), the ASD group showed a significantly delayed response downstream in the inferior frontal lobe (Broca's area), coupled with reductions in the amount of activity in the inferior frontal lobe as well as primary motor cortex (Nishitani et al. 2004). Results from another study revealed that the typical increase in beta (15–25 Hz) activity that occurs after an individual observes an action (the “postmovement beta rebound”) was reduced in adults with ASD in multiple regions in the mirror neuron system, including sensorimotor cortex, premotor cortex, and the superior temporal gyrus, as well as in the medial prefrontal cortex (Honaga et al. 2010).

Face Processing

Despite an extensive literature reporting face-processing abnormalities in ASD using fMRI, only two studies to date have examined face processing in ASD using MEG. One compared the processing of faces to that of mugs and geometrical patterns in adults with ASD (Bailey et al. 2005). Results indicated that the neuromagnetic response to faces at short latencies (30–60 ms) is abnormal in ASD, and equivalent current dipole estimation revealed abnormal face-processing loci in ASD. The second study examined face processing in children with ASD, specifically with respect to processing of faces with direct versus averted gaze (Kylliäinen et al. 2006). Findings demonstrated that at early latencies (up to 100 ms), neuromagnetic activity was similar in the ASD and control groups, save a lack of repetition priming in ASD. However, at longer latencies, group differences were more pronounced, with greater responses in ASD to direct versus averted gaze at 240 ms poststimulus (a pattern inconsistent with that of the control group) and weaker responses at 300 ms poststimulus in ASD compared to controls.

Somatosensory System

Only two studies to date have examined the somatosensory system in ASD. Examining young adults with ASD, one study (Coskun et al. 2009a) investigated the variability of evoked responses to tactile stimulation and failed to find

abnormalities in the ASD group. The other study examined the organization of somatosensory cortex via somatic maps and found abnormal cortical organization in young adults with ASD. Specifically, the cortical representations of the thumb and lip were further apart in the ASD group compared to the control group (Coskun et al. 2009b).

Auditory/Language Processing

The majority of the ASD MEG literature to date capitalizes on the ability of MEG to detect lateralized superior temporal gyrus (STG) activity in order to characterize auditory functioning in ASD, with the goal of elucidating biomarkers associated with language impairment in ASD. A number of studies have investigated auditory evoked responses to simple tones, with the hypothesis that impairments in the processing of simple auditory stimuli early in life would likely have cascading detrimental effects on language development. The evoked response most often examined is the M100, a ~100-ms response elicited in passive listening paradigms that is modulated by stimulus parameters such as frequency. Several studies have shown abnormalities in the M100 response in children with ASD. Among these abnormalities are prolonged M100 latencies (Gage et al. 2003; Gandal et al. 2010; Roberts et al. 2010), abnormal hemispheric asymmetry of the M100 (Schmidt et al. 2009), and abnormal modulation of the M100 by tones of different frequencies (Gage et al. 2003).

Another feature of auditory processing in ASD that MEG studies have revealed to be abnormal is the mismatch field (MMF). The MMF occurs approximately 200 ms after an auditory stimulus and is a measure of acoustic change detection obtained by subtracting the evoked response to a frequently presented standard stimulus from the evoked response to an infrequently presented deviant stimulus. The presence of an MMF indicates passive, preattentive discrimination of the standard and deviant stimuli. MEG studies have demonstrated latency delays in the MMF in children (Oram Cardy et al. 2005; Roberts et al. 2011) and adults (Kasai et al. 2005) with ASD as well as reduced amplitude, or even absence, of the MMF in children with ASD (Tecchio et al. 2003).

The M100 and MMF abnormalities may provide insight into the language impairments characteristic of ASD in that atypical early acoustic processing may have cascading downstream effects on the processing of language, which is inherently more complex and involves processing acoustic units presented in rapid temporal succession. Results from an MEG study of auditory processing of pairs of tones support this hypothesis; in children and adolescents with ASD, the majority of those with language impairment failed to show evoked responses to the second of two tones when the two tones were presented in rapid succession (Oram Cardy et al. 2005).

Future Directions

A number of novel approaches to the study of neural abnormalities in ASD are emerging in the MEG research community. One such approach is the study of resting-state neuromagnetic activity, which has the potential to shed light on abnormal patterns of neural activity in ASD in the absence of specific sensory processing. In addition, analyses of functional connectivity, or interactions between brain regions, both in the resting state and in sensory and cognitive processing are being implemented with increasing frequency. Functional connectivity analyses have the potential to provide insight into neural abnormalities in ASD at the network level. A clear benefit of MEG in this area of research is the ability to examine network interactions at multiple frequencies and with fine-grained temporal resolution.

Other exciting new applications of MEG in ASD research involve multimodal integration of MEG and complementary neuroimaging techniques, including diffusion tensor imaging (DTI) and magnetic resonance spectroscopy (MRS). Multimodal MEG and DTI studies afford the opportunity to investigate associations between electrophysiological measures (e.g., delayed auditory evoked 100-ms responses) and the structural integrity of white matter tracts. Multimodal MEG and MRS studies allow for investigation into associations between electrophysiological measures and neurotransmitter levels. Two particularly

promising targets in ASD research are GABA and glutamate. With the growing number of applications of MEG to ASD research emerges the potential to develop multidimensional classifiers that will help to further elucidate the neuropathology of ASD.

Maintenance of Treatment Effects

Leona Oakes

Department of Clinical and Social Sciences in Psychology, University of Rochester, Rochester, NY, USA

Synonyms

[Durability of treatment effects](#); [Sustained treatment benefits](#); [Treatment gain retention](#)

Definition

The continued improvement in functioning and/or use of skills gained through an intervention over time. Maintenance of behavior change may be strengthened through procedures such as the occasional use of the intervention methods originally used to promote behavior change, provision of reinforcement for displaying the newly learned behavior, and overlearning (teaching until the learner is fluent at displaying the new behavior). Maintenance of treatment effects is often addressed alongside generalization of skills to maximize the retention of treatment gains.

Maladaptive Behavior

Sarah A. O. Gray

Department of Psychology, University of Massachusetts Boston, Boston, MA, USA

Department of Psychology, Tulane University, New Orleans, LA, USA

Synonyms

[Problem behaviors](#)

Definition

Maladaptive behavior is defined as behavior that interferes with an individual's activities of daily living or ability to adjust to and participate in particular settings.

Maladaptive behaviors lie along a spectrum from more minor, less impairing behaviors (i.e., nail biting, difficulty separating) to more severely impairing behaviors (i.e., self-injurious or oversexualized behaviors) that seriously interfere with individuals' ability to maintain relationships with others, learn, and/or engage in adaptive, age-appropriate activities and settings. Because of their impairing nature, maladaptive behaviors are often the target of interventions. Problem behaviors are often a concern for children with developmental disabilities; maladaptive behaviors commonly associated with autism spectrum disorders include self-injurious behaviors (e.g., headbanging), stereotypies, aggression, and temper tantrums.

Although maladaptive behavior is related to adaptive behavior, or the personal and social skills necessary for day-to-day functioning, these two domains are distinct both conceptually and functionally. Thus, maladaptive behavior is not simply defined as the *absence* of adaptive behavior; reciprocally, adaptive behavior is not the absence of maladaptive behavior.

Maladaptive behavior is a term that is used most often in the discussion of adaptive behavior. In other contexts, maladaptive behaviors are usually considered under a broader umbrella of social-emotional and behavior problems that are measured with checklists.

Mand Fluency Training

Corey Ray-Subramanian
Waisman Center, University of
Wisconsin-Madison, Madison, WI, USA

Definition

Mand fluency training, or mand training, is an intervention approach designed to teach individuals with limited communication skills to express their needs and wants. A mand commonly takes the form of a request and is defined as a verbal act that is reinforced by a specified consequence (Skinner 1957).

Historical Background

Mand training is based on B. F. Skinner's (1957) operant conditioning framework for analyzing the functions of verbal behavior. This behavioral approach to language training has been used extensively with individuals with developmental delays and autism, in particular, as part of early behavioral intervention programs. For example, intervention programs developed by Lovaas (2003) and Sundberg and colleagues (Sundberg

Dominick, K. D., Davis, N. O., Lainhart, J., Tager-Fusberg, H., & Folstein, S. (2007). Atypical behaviors in

and Partington 1998) incorporate mand training as a key component for teaching early communication skills.

Rationale or Underlying Theory

Within an operant conditioning framework, mands are controlled by a motivative variable, often referred to as an establishing operation (Sundberg and Michael 2001). For example, hunger and the desire for a cookie may lead an individual to say “I want a cookie.” This behavior is then reinforced by the offering of a small piece of a cookie. A mand training approach can be contrasted with a traditional language perspective that emphasizes teaching the individual the meaning of different words (e.g., learning to say “cookie” when shown a cookie or “ball” when shown a ball; Sundberg and Michael 2001). It has been suggested, however, that some children with autism do not spontaneously request items even if they have demonstrated understanding of the appropriate word for an item and, thus, need to be explicitly taught this skill (Sundberg and Michael 2001). Because of the unique reinforcement provided through the establishing operation, mand training can facilitate children’s willingness to participate in language training, in general (Sundberg and Michael 2001).

Goals and Objectives

The ultimate goal of mand training is to increase an individual’s spontaneous requesting behavior so that the individual can make his or her needs and wants known to others. Short-term objectives may include imitating mands and requesting basic items, such as food within sight. Longer-term objectives may include requesting items or activities that are not present in the immediate environment.

Treatment Participants

Participants in mand training are individuals, typically young children, with developmental

disabilities who have limited expressive language skills and who do not spontaneously make verbal requests to express their needs and wants.

Treatment Procedures

Mand training can be used as part of a larger early intervention program focused on developing language, cognitive, self-help, and play skills. For example, the *I Want* program (Lovaas 2003), which is one component of a large package of intervention techniques for individuals with developmental delays, is designed to teach participants to verbalize their choices when presented with desired and undesired items and to develop spontaneous verbal requesting behavior. The developer of the program recommends starting with teaching the participant to request his or her favorite foods, objects, or activities to reinforce the behavior and possibly reduce problem behavior resulting from frustration with not being able to communicate desires (Lovaas). If necessary, the individual would first need to be taught how to imitate several “I want (item)” statements (e.g., *I want ball*, *I want cookie*, *I want juice*). The participant is then presented with the stimulus “What do you want?” and prompted to say “I want juice,” for example. The participant’s response is then reinforced by having access to a small amount of the item (e.g., a sip of juice, 5 s of playtime with the ball). As the participant reaches specified accuracy benchmarks, the prompts are faded and new items are introduced. Eventually the participant is prompted to request items that are not in sight and then progresses to being reinforced systemically for spontaneous requests that are not prompted. For individuals who are unable to echo sounds or imitate actions, mand training can be done using signs or pictures.

Important issues to include when selecting initial words for mand training include:

- (a) Choosing words that will be reinforcing to the participant and that the instructor can easily control, have access to, and that can be delivered multiple times

- (b) Selecting words the participant can imitate or for which the individual has demonstrated understanding
- (c) Choosing words that are relatively easy for the participant to say
- (d) When using sign language, selecting signs that look like the objects they represent and that the individual can already imitate
- (e) Choosing words for items that are relevant to the participant's daily life
- (f) Selecting words for a variety of motivators (e.g., not all foods)
- (g) Avoiding words that sound alike or rhyme
- (h) Avoiding words that may represent something negative for the individual (Sundberg and Partington 1998)

Efficacy Information

Mand training is often implemented as part of a broader behavioral intervention program, and its efficacy has not been examined extensively in isolation. However, smaller studies have provided some evidence for the efficacy of mand training in children with autism (e.g., Drash et al. 1999). There is also some evidence that it may be more efficient than discrete trial instruction for facilitating the acquisition of requesting behavior (Jennett et al. 2008). Adding opportunities for rapid imitation of modeled motor behaviors during mand training has been shown to increase the efficacy of mand training, with evidence of increased spontaneous manding 3 months later (Ross and Greer 2003). In general, however, there is limited information from published studies on the long-term generalization of skills taught during mand training.

Outcome Measurement

Efficacy research on mand training has utilized various metrics for progress monitoring and outcomes measurement, such as specified trial accuracy criteria (e.g., 9 out of 10 correct responses), percentage of correct responses, percentage of incorrect responses, or the number of spontaneous

mands in a given period. Clinical intervention programs that include mand training typically use specific accuracy criteria for determining when an individual is ready to progress to the next stage (e.g., from imitating mand to being expected to produce them when prompted).

Qualifications of Treatment Providers

Mand training providers are typically professionals or supervised paraprofessionals with formal training in behavioral theory and applied behavioral analysis techniques. In some verbal behavior programs, parents and caregivers are also taught basic mand training techniques to facilitate generalization of the individual's skills beyond the therapy context.

Definition

Mands are verbal acts that are reinforced by a specified consequence (Skinner 1957). This term was introduced by B. F. Skinner and refers to a specific type of verbal action within an operant conditioning framework designed to analyze the functions of verbal behavior. Mands are considered to be the first type of verbal behavior that individuals typically acquire (Sundberg and Michael 2001). As part of a verbal behavior training intervention, mands commonly take the form of requests for items, information, or removal of aversive stimuli (Sundberg and Michael 2001). For example, if an individual who wants a cookie says “Cookie, please” and is then given a cookie, the individual’s statement (i.e., “Cookie, please”) would be considered a mand.

Short Description or Definition

The American Psychiatric Association (APA) Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) defines a manic episode as “a distinct period during which there is an abnormally and persistently elevated, expansive, or irritable mood” (American Psychiatric Association [APA] 2000, p. 357). Symptoms of mania include a high activity level which may be directed toward a specific goal or may consist of psychomotor agitation, inflated self-esteem, a decreased need for sleep, racing thoughts, talkativeness, distractibility, and engaging in pleasure-seeking activities without regard for consequences. Individuals experiencing mania are often noted to have a change in personality, in which they become reckless, boisterous, and engage in high-risk activities. If the individual’s mood is elevated, three of the prior symptoms are required; four if the mood is irritable. To qualify as a manic episode in DSM-IV-TR, the episode must last at least one week, or any duration if symptoms are severe enough to require hospitalization, and must result

in impairment in the ability to function in daily life. Psychotic features, including delusions (false beliefs) or hallucinations, may be present. The manic episode cannot be caused by the effects of drugs of abuse, medications, exposure to a toxic substance, or a general medical condition (APA 2000).

Categorization

A manic episode is one of the essential components of bipolar I disorder, which historically has been referred to as manic-depressive disorder. Although bipolar I disorder usually also includes episodes of depression, it is the occurrence of the manic episode that is the defining feature. A hypomanic episode is a less severe form of mania, which is not severe enough to cause substantial impairment in functioning in daily life, does not necessitate hospitalization, and there are no psychotic symptoms. Bipolar II disorder is characterized as a mood disorder in which hypomania, as opposed to mania, is present (APA 2000).

Epidemiology

The lifetime prevalence of bipolar I disorder in the community is estimated at 3.9% (Perlis et al. 2004). There is less diagnostic clarity when the mood symptoms have their initial symptoms presenting in childhood, as many other disorders have overlapping symptoms. Twenty is the mean age of onset for a first manic episode, but retrospective studies suggest that about 60% of adults with bipolar disorder demonstrated some mood symptoms in childhood or adolescence. There has been a trend over time for the age of the first onset of symptoms to occur earlier in life. For adolescents who have suffered from recurrent major depression, about 10–15% will experience a manic episode and thus develop bipolar I disorder (Boris et al. 2007). The lifetime prevalence of bipolar I disorder in the community is estimated at 3.9% (Perlis et al. 2004). There is less diagnostic clarity when the mood symptoms have

their initial symptoms presenting in childhood, as many other disorders have overlapping symptoms. Twenty is the mean age of onset for a first manic episode, but retrospective studies suggest that about 60% of adults with bipolar disorder demonstrated some mood symptoms in childhood or adolescence. There has been a trend over time for the age of the first onset of symptoms to occur earlier in life. For adolescents who have suffered from recurrent major depression, about 10–15% will experience a manic episode and thus develop bipolar I disorder (Boris et al. 2007).

Men and women suffer from bipolar I disorder in about equal numbers. However, women more commonly have a major depressive episode first and suffer from more depressive episodes than manic episodes, whereas men most often experience their first episode as mania and have more equal numbers of manic and depressive episodes. Manic episodes frequently occur after a stressful life event. In about 2/3 of cases, a manic episode immediately follows or precedes an episode of major depression. Most individuals have periods of more normal mood states between episodes of either mania or depression. However, about one-quarter of individuals with bipolar I disorder more persistently display a labile (fluctuating) or irritable mood (APA 2000). In individuals over the age of 13 who are diagnosed with autism, approximately 3% suffer from manic episodes (Howlin 2005).

Natural History, Prognostic Factors, and Outcomes

Mania, associated with bipolar disorder is a recurrent illness. In general, the earlier the age of onset of the disorder (either depressive or manic symptoms), the more recurrent and chronic the course of illness. Recovery from the first manic episode is very high (over 70%), but a similar number (up to 80%) will experience recurrence of the disorder within 2–5 years.

Early-onset bipolar disorder also has a high rate of persistent lower level mood symptoms. Child and adolescent onset of the disorder is often characterized by more rapid fluctuations in

mood than when the disorder is not evidenced until adulthood.

Poor prognostic factors for manic episodes are early age of onset, long duration of symptoms, exposure to trauma and negative life events, low socioeconomic status, mixed or rapid cycling episodes, psychotic symptoms, and co-occurring psychiatric disorders. Suicidal ideation and attempts occur most often when an individual is depressed or using substances. For individuals with bipolar I disorder, the completed suicide rate is estimated at 10–15% (Geller et al. 2004).

Clinical Expression and Pathophysiology

Elevated mood is the cardinal symptoms of mania. Individuals who experience mania often feel so elated and omnipotent that they do not recognize that they are ill in any way. It is those around them that notice the change in behavior. The manic individual often demonstrates poor judgment, may change personal appearance to a flamboyant style that is out of character, and may exhibit high-risk behaviors, such as sexual promiscuity, substance use, or spending large sums of money. For youth presenting with mania, increased energy, distractibility, and pressured speech are the most common symptoms, while hypersexuality has been found to be the least frequent (Boris et al. 2007).

Very severe mania often includes psychotic symptoms. More than half of manic individuals experience delusions, usually of grandeur (the false belief that one is famous, has unusual powers, or is special in some other way). Religious delusions are also common. Hallucinations, usually auditory, occur in about one-fourth of individuals. Some individuals may experience symptoms of mania and major depression that alternate rapidly, with both experienced almost every day. This is referred to as a “mixed episode.” Agitation, insomnia, rapid changes in appetite, psychotic features, and suicidal thoughts are frequent symptoms for individuals with mixed episode mood disorders (APA 2000).

Although there are no specific laboratory tests that are diagnostic of a manic episode, some

abnormal test results are frequently found in individuals with mania. These include abnormal polysomnograms (electroencephalograms or EEGs that occur during sleep) and increased cortisol secretion. Studies of neurotransmitter metabolites, neuroendocrine function, and pharmacological challenges suggest that there may be abnormalities of many of the central nervous system neurotransmitters: norepinephrine, serotonin, acetylcholine, dopamine, and gamma-aminobutyric acid (GABA).

Bipolar disorder has been demonstrated to run in families, according to multiple twin and adoption studies. Having a first-degree relative who has been diagnosed with bipolar disorder confers an increased risk (eight- to tenfold over community samples) of also being diagnosed with the disorder. Symptoms typically occur at an earlier age in children with a close family history of bipolar disorder. The heritability for bipolar disorder has been estimated at over 80% (Boris et al. 2007).

Evaluation and Differential Diagnosis

The evaluation for mania includes a patient interview, collateral information from significant others, a medical workup, gathering family history of mood disorder, and the use of assessment scales (see Table 1). Structured and semi-structured interviews (SADS or for children the K-SADS) or a general checklist, such as the Child Behavior Checklist (CBCL), may be helpful diagnostically and for research purposes. For youth, the Young Mania Rating Scale (Young et al. 1978) is the most widely used. Also for youth, parental report is more effective in identifying mania than youth or teacher reports. The Parent Mood Disorder Questionnaire (MDQ) is a widely used rating scale. Mood timelines or diaries may help track mood symptoms, and may also identify events that trigger these symptoms and document response to treatment (Nandagopal and DelBello 2011).

Many other disorders have overlapping symptoms with early-onset bipolar disorder. Attention-deficit/hyperactivity disorder, disruptive behavior disorders and conduct problems, substance abuse disorders, schizophrenia, and pervasive developmental disorder with irritability are most common.

Mania, Table 1 Components of a diagnostic evaluation for mania

Chief complaint	From patient, family, significant others, referral source
Context	In what context does mania occur?
Multiple informants and collateral history	History of symptoms from family, significant others, referral source, primary care physician, etc. (with patient consent or from legal guardian if patient is a minor)
Timeline of mood symptoms	Frequency, intensity, number, and duration (FIND) of mood episodes
Developmental, social, and family history	Developmental milestones, educational history, level of functioning, social relationships, medical history, and family history of psychiatric disorders
Patient interview/mental status examination	Developmentally appropriate interview. Inquire about substance use, high-risk behaviors, suicidality and homicidality, legal problems, trauma history, sleep, and energy level. Assess for psychotic symptoms
Medical evaluation	Routine physical examination; further medical evaluation as indicated: illicit substances (toxicology screen); toxic (lead or toxin levels); autoimmune diseases (screen for lupus, and others); neurological (EEG for epilepsy; brain imaging for multiple sclerosis, etc.); metabolic/infections (thyroid levels, liver function tests, complete blood count, etc.); other diseases (e.g., Cushing's disease by cortisol level)
Rating scales	SADS, K-SADS, Young Mania Rating Scale, Child Behavior Checklist (CBCL), Parent Mood Disorder Questionnaire (MDQ)

Mania, Table 2 Treatment of mania

Treatment: pharmacotherapy	
Lithium	Most evidence base for effectiveness in adults and adolescents. Used as monotherapy or in combination with an antipsychotic or anticonvulsant medication
Anticonvulsant medications: valproate, carbamazepine, lamotrigine, oxcarbazepine, topiramate	The most evidence for effectiveness in adults and adolescents are with valproate, carbamazepine, and lamotrigine. Used as monotherapy or in combination with lithium or an antipsychotic
Atypical antipsychotic medications: olanzapine, risperidone, quetiapine, aripiprazole, clozapine, ziprasidone	May be used as monotherapy but are often used to target symptoms of psychosis or for more rapid treatment response in conjunction with lithium or an anticonvulsant medication
Treatment: psychosocial	
Environmental	Safe and less stimulating environment, sleep hygiene, and routine. For severe mania, this may include psychiatric hospitalization
Psychoeducation and support	Active listening; restoration of hope; case management (collaborate with school, job, community resources, family regarding needed services); education about causes, symptoms, treatment, and prognosis
Therapeutic interventions	Day treatment or partial hospitalization program; individual therapy: cognitive-behavioral therapy, dialectic behavioral therapy, interpersonal therapy, supportive therapy; family therapy; skill-building groups

Medical disorders that may present with manic symptoms include hyperthyroidism, head trauma, brain tumors, or Cushing's syndrome. Medications, such as corticosteroids, antidepressants, and

stimulants, may be accompanied by mood fluctuations or precipitate manic symptoms.

In individuals diagnosed with autism spectrum disorders, the most common other psychiatric

diagnoses are attention-deficit/hyperactivity disorder, depression, and anxiety disorders, with mania occurring with no more frequency than the rest of the population (Howlin 2005; Matson and Nebel-Schwalm 2007).

Treatment

Current treatments for mania aim to control the agitation, impulsivity, aggression, and psychotic symptoms and to help patients regain their pre-illness level of functioning. After the first episode of mania, many individuals demonstrate ongoing milder levels of dysfunction, which may or may not resolve fully. Mania, and thus, bipolar I disorder, is a recurrent disorder, and effective treatment must include acute, continuation, and maintenance phases. Effective treatment includes the use of appropriate medications in the mood stabilizing, antiepileptic, and antipsychotic classes. These medications may be used in monotherapy or combined for enhanced effectiveness. Psychosocial interventions, including education about the disease, case management and coordination of services, family therapy, group therapy, and individual supportive and evidence-based treatments are also essential to optimize prognosis. Table 2 highlights the components of effective treatment.

Synonyms

[American Sign Language \(ASL\)](#); [Conceptually accurate signed english \(CASE\)](#); [Linguistics of verbal english \(LOVE\)](#); [Manually coded english \(MCE\)](#); [Seeing essential english \(SEE I\)](#); [Sign language](#); [Signed english](#); [Signing exact english \(SEE II\)](#)

Definition

Manual sign is a system of communicating visually and spatially through signs created with the hands. The term “manual sign” does not specify a particular sign system such as American Sign Language (ASL) or manual codes of English such as Seeing Essential English (SEE I), Signing Exact English (SEE II), Linguistics of Verbal English (LOVE), and Conceptually Accurate Signed English (CASE). ASL is the natural language of the deaf community in the United States and much of Canada (Neidel et al. 2000). ASL is a distinct language from spoken English (see entry on ► [“American Sign Language \(ASL\)”](#)) while manual codes of English are based on spoken English and are an attempt to represent English on the hands. Manual codes of English were created in the 1960s primarily to aid in increasing the literacy skills of deaf and hard-of-hearing children (Schow and Nerbonne 2007). Manual codes of English can be classified as “sign systems” and not “sign languages” because they borrow the semantics and syntax from spoken English. These sign systems follow English word order and use grammatical markers for morphological endings of words. For example, the word “smiling” is signed with two signs SMILE + ing. Additionally, unlike ASL, manual codes of English use signs for function words such as “the” and “an.” Typically, when signing is employed in the language intervention for children with autism, the type of signing systems that are used is manual codes of English rather than ASL. The main reason for this may be the hope that using manual sign will lead to verbal communication, an outcome which has been supported by research (Schlosser and Wendt 2008).

Massed Practice

Anjileen Singh
Counseling, Clinical, and School Psychology, UC
Santa Barbara, Santa Barbara, CA, USA

Definition

The repeated presentation of a task over a short period of time, with no intertrial interval between presentations. The term was first introduced by Hermann Ebbinghaus, and a detailed study was published in the 1885 book *Memory: A Contribution to Experimental Psychology*. Since then, researchers have found that distributed

practice, or spaced practice, in which short periods of learning are interspersed with periods of rest or alternative activities, produces better performance than massed practice in a variety of tasks (Hunter 1929).

Studies investigating the influence of task variation on learning suggest that distributed practice produces superior levels of on-task responding and higher levels of child affect in children with autism (Dunlap 1984). Researchers suggest that interspersing alternative activities with varying difficulty levels serves to increase the child with autism's motivation to respond to the tasks (Koegel and Egel 1979).

Massed practice can also refer to a self-directed behavior change technique in which a person performs an undesired behavior repeatedly, which sometimes decreases the future frequency of the behavior (Cooper et al. 2007).

[Mastocyte](#)

Definition

Despite the increase prevalence of autism spectrum disorders (ASD), the pathogenesis and therapeutic options for ASD remain poorly understood (Theoharides et al. 2012). In recent years, several reports have suggested the importance of brain inflammation in the pathogenesis of several psychiatric conditions (Theoharides et al. 2016). Among ASD patients, many develop worsening symptoms after vaccination, infections, toxins, or other environmental exposures suggesting an underlying immune dysregulation (Theoharides et al. 2016). Specifically, increased inflammatory cytokines, autoantibodies, and allergic responses reported in ASD patients suggest mast cells may have a prominent role in the onset and progression of ASD (Theoharides et al. 2016). Patients with increased mast cells have an increased prevalence of ASD and other cognitive deficits, suggesting an underlying mast cell hyperactivity among ASD patients (Theoharides 2013). Mast cells are bone marrow-derived cells that modulate the innate immune response and contribute several chronic inflammatory and renal diseases (Balakumar et al. 2009; Holdsworth and Summers 2008; Wasse et al. 2012). Within the central nervous system, mast cells are

Massive Infantile Spasms

- [Infantile Spasms/West Syndrome](#)

concentrated in the diencephalon, which modulates several emotional and behavior responses (Theoharides et al. 2016). In recent years, mast cell interactions with microglial have been implicated in the pathogenesis of ASD and other neuroinflammatory and psychiatric disorders (Theoharides et al. 2016). Several studies suggest neuroinflammation interferes with mast cell-microglial interactions from pruning neural circuits during neurodevelopment producing abnormal microglial growth and activation in ASD patients (Theoharides et al. 2016). Specifically, environmental and psychological stresses during prenatal development may stimulate the release of potent neuropeptides, neurotensin, and corticotropin-releasing factor and stimulate mast cells to increase vascular permeability and disrupt the blood-brain barrier in ASD patients (Theoharides et al. 2016). With the lack of effective treatments for ASD, pharmacological treatments targeting mast cell-microglial interactions may provide a new treatment options for ASD patients and their caregivers (Tsiloni et al. 2015).

Maternal and Child Health Bureau

Cynthia Zierhut and Sally J. Rogers
Department of Psychiatry and Behavioral Sciences, UC Davis M.I.N.D. Institute, Sacramento, CA, USA

Major Areas or Mission Statement

The Maternal Child Health Bureau (MCHB), a United States Federal commitment to addressing maternal and child health, was first established in 1912. In 1935, the MCHB was transferred to Title V of the Social Security Act and then converted to a federal block grant administered by the Health Resources and Services Administration (HRSA) in 1981. The mission of the MCHB is to provide leadership, in partnership with key stakeholders, to improve the physical and mental health, safety, and well-being of the nation's women, infants, children, adolescents, and their families, including fathers and children with special health-care needs.

Landmark Contributions

HRSA administers a wide range of programs to pregnant women, mothers, infants, children, and their families. MCHB programs serve more than 34 million women, infants, and children each year in the United States. The MCHB supports programs to reduce infant mortality by providing comprehensive prenatal and postnatal care for women, promotes an advocacy community-based group for Healthy Start programs, and is a proponent of preventative care (including rehabilitative services and immunizations) for children, research and training, genetic services, and newborn screening and treatments.

The HRSA awards grants to improve health care and other services for children and adolescents with autism spectrum disorders and other developmental disabilities. Funds are utilized to enhance awareness and reduce barriers to screening and diagnosis. Funds also support research of evidence-based interventions, evidence-based guidelines for interventions, training professionals to use valid screening tools for diagnosis and intervention, and improving technical assistance to facilities which provide services for children with autism spectrum disorders.

Major Activities

HRSA's implementation of the Combating Autism Act of 2006 (\$48 million) addresses the most urgent issues affecting people with autism and their families. The goal of this act is to enable all infants, children, and adolescents who are at risk for developing or who have autism spectrum disorders and other developmental disabilities to reach their full potential by:

- Establishing a system of services, including early screening of children for autism spectrum disorders
- Conducting early, multidisciplinary evaluations to diagnose or rule out autism spectrum disorders
- Providing evidence-based early interventions when a diagnosis is confirmed

Maternal Hypothyroidism and Autism

Stephen Sulkes

Division of Developmental and Behavioral Pediatrics, Golisano Children's Hospital, University of Rochester, Rochester, NY, USA

Synonyms

Iodothyronine deiodinase (D2T3); Thyrotropin, Thyroid-stimulating hormone (TSH); Thyroxine (T)

Structure

The thyroid gland is part of the endocrine system. It regulates the rate of metabolism and impacts growth by its regulation of other tissues through secretion of hormones triiodothyronine (T3) and thyroxine (T4). The substrates these hormones are synthesized from are iodine and tyrosine. The rate that these hormones are produced is regulated by thyroid-stimulating hormone (TSH) from the anterior pituitary gland. TSH is itself regulated by thyrotropin-releasing hormone (TRH) produced by the hypothalamus. The fetus begins to make T3 at 18–20 weeks' gestation and T4 by 30 weeks. This may be partially protective from maternal hypothyroidism.

Function

Thyroid hormones are critical to normal brain development.

The thyroid regulates metabolism and growth and impacts both calcium metabolism and catecholamine effects.

Typical symptoms of hypothyroidism (low hormone production) postnatally are decreased energy, constipation, weight gain, fatigue, cold intolerance, hair loss, and slowed heart rate. Typical symptoms of hyperthyroidism (increased hormone production) postnatally are mood swings, overactivity, decreased appetite, and increased heart rate.

Pathophysiology

Among the prenatal conditions that have been associated with autism spectrum disorders is prenatal exposure to maternal hypothyroidism. Although not clearly demonstrated as a cause of autism, this hypothesis has growing support from neuroembryonic research, and some have suggested links between environmental toxins, maternal hypothyroidism, and the autism “epidemic.”

Twenty-five years ago, Gillberg et al. (1992) noted that congenital hypothyroidism was associated with autism spectrum disorders, along with intellectual disability and other physical concerns. In 1999, Haddow et al. confirmed that children exposed in utero to maternal hypothyroidism manifesting as high gestational thyrotropin (thyroid-stimulating hormone, or TSH) levels, arising in response to relative low levels of thyroid hormone, resulted in significant neuropsychologic impacts at school age. Developmental abnormalities were present even in children of women whose hypothyroidism was subclinical or partially treated (Bernal 2007).

Thyroid hormone receptors are present in the fetal cortex by 8–9 weeks of gestation and increase tenfold by 18 weeks (Bernal 2007), and brain T₃ and iodothyronine deiodinase (D₂) activities increase during the second trimester (Kester et al. 2004). D₂ is felt to play an important role in brain compensation for variations in ambient thyroid hormone levels. It is well established that thyroid hormone plays a role in brain development during the fetal period, that different parts of the brain are differentially sensitive to thyroid hormone at any one time during development, and that sensitivity to

thyroid hormone is controlled, in part, by local control of hormone production. These observations imply that the consequences of thyroid hormone insufficiency during fetal development differ from those of thyroid hormone insufficiency during postnatal development (Zoeller 2005). However, it has also been shown that small fluctuations in maternal thyroid hormone levels can have measurable neurocognitive impacts on the developing fetus. One impact of hypothyroidism shown in animal models is reduced expression of reelin, which regulates neuronal migration (Alvarez-Dolado et al. 1999). Abnormality of reelin expression has been associated with ASDs (Fatemi et al. 2005), and although not universally accepted, abnormalities of reelin genes have been associated with ASDs (Serajee et al. 2006; He et al. 2011).

It has been noted that thyroid hormone deficiency before the onset of hearing has negative effects on peripheral and central auditory systems (Knipper et al. 2000). In animal models, maternal hypothyroidism has been shown to result in abnormal cochlear development, in abnormal neurotransmission in the developing auditory brainstem and hippocampus (Friauf et al. 2008) and in cerebrocortical and hippocampal synaptic activity (Taylor et al. 2008). Based on these and other animal studies, it has been proposed that the rat exposed to mild, transient neonatal hypothyroidism may serve as a model for autism (Sadamatsu et al. 2006).

High TSH levels have also been noted to be associated with increased risk of breech presentation in term infants, based on samples of Dutch women followed for TSH elevation or evaluated for breech presentation (Kooistra et al. 2010). Inasmuch as breech presentation is one risk factor for ASDs (Bilder et al. 2009), this supports the relationship. The authors note that infants who present in the breech position often have low tone or reasons for less active body movements such as kicking and that suboptimal maternal thyroid function might have a direct motor effect on the fetus. Alternatively, they quote literature (Van der Meulen et al. 2008) that suggests that the sensory responses of fetuses in breech position are different from those in cephalic presentation.

Sweeten et al. (2003) replicated the findings of Comi et al. (1999), noting increased frequency of autoimmune disorders, with hypothyroidism being the most common, among parents of children with autism spectrum disorders. They acknowledge that this could be an effect of endocrine abnormality or, alternatively, the result of another immunologic abnormality having a direct effect on brain development. A meta-analysis by Wu et al. (2015) and supported by Brown et al. (2015) reasserted this association based on pooled data, with an increased risk overall and greater risk specifically with maternal hypothyroidism.

An extensive review of the hypothyroidism/ASD association by Román (2007) draws an association between maternal hypothyroidism and neuropathologic features found in individuals with ASDs, including abnormalities in the cortex and hippocampus, “consistent with abnormal neuronal migration and alterations in the number, survival, and orientation of neurons up to the time of olivary cell migration. . . before the end of the third month” of gestation. He notes that, in humans, the fetal thyroid forms about mid-gestation and that maternal dietary iodine deficiency and associated hypothyroidism prior to the third trimester of pregnancy can result in endemic cretinism. Multiple possible causes for both transient and long-term maternal hypothyroidism are proposed, including dietary iodine deficiency, exposure to food-based antithyroid substances (particularly soy products and other foods with high levels of isoflavonoids), and other environmental antithyroid substances (herbicides, PCBs, mercury, and coal derivatives). In follow-up to earlier studies, Román et al. (2013) evaluated 4039 mother-child pairs to determine if there was a correlation between maternal hypothyroxinemia before 18 weeks of gestation and autism risk. A “probable autistic child” was defined based on a score >98th percentile on the Pervasive Developmental Problems subscale of the Child Behavior Checklist in conjunction with a score in the top 5% on an 18-item short-form version of the Social Responsiveness Scale, administered at about age 6 years. Eighty children were defined as being a probable autistic child; the adjusted odds ratio of being a probable autistic

child increased 3.9 times when the mother had severe hypothyroxinemia in early gestation, but there was no relation between mild hypothyroxinemia in the mother and autism in the child. Specific ASD diagnosis was not performed, so a significant limitation in this study is the specificity of parent report of problems. Andersen et al. (2014) reported a retrospective population based cohort study of over 30,000 children born to mothers with thyroid disease that suggested an association between ASD (based on medical record review) and hypothyroidism diagnosed in the mother after birth, suggesting that antibody and TSH exposure prenatally could be a factor.

Colborn (2004) has also been outspoken in drawing an association between endocrine-disrupting synthetic chemicals and neurodevelopmental disorders such as ADHD and autism spectrum disorders. Some environmental chemicals, e.g., perchlorate, which has sometimes contaminated water supplies, directly interfere with iodine uptake into the thyroid gland. Other chemicals interfere with thyroid hormone signaling; polychlorinated biphenyls (PCBs) have this effect. Bisphenol A (BPA), involved in the manufacture of plastics, also blocks thyroid action on glial cells. Blazewicz et al. (2016) found lower urinary iodine levels in boys with ASDs, compared to controls, although thyroid hormone levels and thyroid volumes were comparable, with a correlation between clinical ASD severity and lower urinary iodine levels. Hamza et al. (2013) reported similar findings in both children with ASD and their mothers, also noting lower reported intake of iodized salt. Whether these differences were cause or effect of ASD was unclear.

As Zoeller (2005) notes, “a causal relation between (environmental) contaminants, thyroid hormone signaling, and cognitive development will be difficult to obtain given the fact that even small and transient thyroid hormone insufficiency may be detrimental.” If screening of pregnant women for elevated TSH levels and thyroid supplementation when indicated become routine, epidemiologic studies of autism in the children of these women will be informative. Meanwhile, there is not yet clear evidence to associate prenatal

exposure to maternal hypothyroidism with autism spectrum disorders, nor are there clear links from environmental toxins to maternal hypothyroidism to autism spectrum disorders, but the hypotheses presented are provocative and speak to the need for well-controlled study.

Maternal Obesity and ASD Risk

Yong-Jiang Li¹ and Ya-Min Li²

¹Department of Pharmacy, The Second Xiangya Hospital, Central South University, Changsha, Hunan, China

²Clinical Nursing Teaching and Research Section, The Second Xiangya Hospital, Central South University, Changsha, Hunan, China

Definition

Obesity is a nutritional and metabolic life-course condition with excessive accumulation of adipose tissue that affects health adversely. Body mass index (BMI) calculated as weight in kilograms divided by height in meters squared was used for the definition of obesity. By this measure, obesity is defined as a BMI ≥ 30 kg/m² for adults. Furthermore, BMI values were classified in the following categories: underweight < 18.5 ; normal 18.5–24.9; overweight 25–29.9; obese class I 30–34.9, obese class II 35–39.9; obese class III ≥ 40 according to the National Institute of Health guidelines on obesity and overweight (NIH 1998). While there is no existing definition of maternal obesity during pregnancy, a maternal prepregnancy BMI is used for the classification.

Historical Background

In 2011, Dodds et al. (2011) published their study quantifying the relationship between prenatal, obstetric, and neonatal factors and autism risk. They first reported that prepregnancy weight of 90 kg or more was an independent risk factor for autism. Similarly, Lyall et al. (2011) reported their novel finding that maternal late adolescent BMI ≥ 30 may have a doubling of the risk of ASD in offspring. Since then, a growing number of studies assessing maternal obesity and risk of ASD in offspring have been published (Surén et al. 2014; Reynolds et al. 2014; Gardner et al. 2015; Getz et al. 2016; Connolly et al. 2016; Casas et al. 2017; Andersen et al. 2018) and a weak positive association has been evidenced by meta-analyses that quantitatively summarized the association (Li et al. 2016; Lei et al. 2019).

Previous studies have proposed several plausible mechanisms for explanation of the association observed. Dodds et al. (2011) speculated the role of leptin as leptin levels were high in obese mothers and children with autism were also found to have increased plasma leptin levels, while Lyall et al. (2011) proposed hormonally mediated pathway. But no further finding support these hypothesizes. Later, immunological and genetic factors were raised. Placenta inflammation can induce a systemic fetal inflammatory response and the role of cytokines in ASD has been found (van der Burg et al. 2015), this suggested that obesity activated maternal dysimmunity may increase the risk of ASD (Buehler 2011). Several abnormalities of the gene found in obese mothers were also linked to ASD, such as Apo D (Edlow et al. 2014), gene variants (Sebat et al. 2007), and changes in DNA methylation (Ladd-Acosta et al. 2014). Therefore, obese mothers are likely to pass on de novo mutations that confer risk for ASD (Pinto et al. 2010).

Current Knowledge

Current evidence suggests that maternal obesity slightly increases the risk of ASD in offspring. However, confounding effects should not be

ignored. For example, diabetes mellitus, including both gestational and preexisting diabetes, are often accompanied by obesity. Diabetes have also been evidenced to be a risk factor for ASD (Xu et al. 2014). Meanwhile, genetic susceptibility and other unknown risk factors also exist. Therefore, adjustment of potential confounding factors is important for implication of maternal obesity as an independent risk factor.

The association between maternal obesity and ASD risk in offspring may be simultaneously mediated by multiple factors and the explicit mechanism needs further elucidation. Often, maternal obesity is a cause of several other consequences that may play as mediators in the association. Besides, several maternal lifestyle factors, such as fat intake, that associated with ASD risk may also affect obesity (Lyall et al. 2013). Studies need to be methodologically rigorous and comprehensive so as to minimize the influences of other risk factors.

Future Directions

As immunological, genetic, and metabolic factors are involved in the pathogenesis of ASD, hypothesis-guided investigations are encouraged. Of proposed mechanisms, inflammatory factors are the most frequently mentioned and may be predominant. Also, potential mediators are required to be further identified for disentangling maternal obesity as a risk factor for ASD.

Maternal Opioid Prescription in Autism Spectrum Disorder

Eric Rubenstein
Waisman Center, University of Wisconsin-Madison, Madison, WI, USA

Definition

Since 2000, both prevalence of identified ASD and the proportion of pregnant women receiving an opioid prescription during pregnancy have increased dramatically. Current evidence suggests a possible association between maternal opioid prescription and ASD identification; yet, few studies of outcomes for children exposed to opiates in utero have had the statistical power or

longitudinal duration to assess autism as an outcome. As opioid use continues to be a research priority in the USA, better data will be available to understand the relationship between prescription and/or illicit opioid use and risk of autism.

Historical Background

The prevalence of ASD identified in population-based samples in the USA has increased consistently in the previous two decades (Autism and Developmental Disabilities Monitoring Network Principal Investigators 2007; Baio et al. 2018; Nevison et al. 2018). While some of this increase is attributable to changing diagnostic patterns (Coo et al. 2007; King and Bearman 2009) or increasing accumulation of ASD-like traits across generations (Connolly et al. 2019; Rubenstein and Chawla 2018; Virkud et al. 2009), there is still a component of ASD risk attributable to negative environmental exposures perinatally (Lyll et al. 2017). Here, the “environment” refers to factors that are not genetic (although genetic factors may also be affected by the environment) and include a person’s physical environment, social and cultural environment, and lifestyle choices (Rothman et al. 2008). Identifying which exposures are linked to ASD adds to the understanding of biological mechanisms that cause ASD and enable development of targeted therapeutics to prevent some impairing aspects, associated features, and co-occurring conditions of ASD.

One such perinatal exposure that has increased in prevalence over the past two decades in the USA is the prescription and use of opioid medication. In a study using Medicaid claims from 2000 to 2007, researchers found that 22% of pregnant women received an opioid prescription at any point during pregnancy (Desai et al. 2014). In a study of women with commercial health plans between 2005 and 2011, researchers found that 14% of women received an opioid prescription (Bateman et al. 2014).

Opioids are a class of drug that binds to opioid receptors in the brain and body causing a reduced perception of pain. While often prescribed to manage short-term pain, opioids can be highly

addictive and are often overprescribed (Lind et al. 2017). Opioid use during pregnancy (whether prescribed or illicit) has been seen to be associated with preterm birth, specific birth defects, poor fetal growth, neonatal abstinence syndrome, and poor child development at 6 months (Broussard et al. 2011; Lind et al. 2017; Norgaard et al. 2015; Nygaard et al. 2015; Sundelin Wahlsten and Sarman 2013; Yazdy et al. 2015). Much research and public health attention has been paid to the “opioid epidemic” (Gostin et al. 2017); yet, there had been limited opportunity to study longitudinal childhood outcomes for children exposed to opioids in utero (Reddy et al. 2017). Preliminary studies have assessed ASD as an outcome identified later in childhood in specific samples, but in building large, longitudinal cohorts, evidence can be further clarified, especially among illicit opioid users.

Potential Mechanisms

Exposure to opioids in utero may alter fetal development through a few hypothesized mechanisms. One such mechanism is based on opioids being small lipophilic molecules that can cross the placental and blood-brain barrier. Therefore, a fetus is at risk if the mother is exposed (Hudak et al. 2012). When exposed to an opioid, the fetal brain structure and function, specifically synaptic plasticity and neural connectivity, may be altered (Ross et al. 2015). Alteration in synaptic plasticity has been shown to be associated with development of autistic traits (Bourgeron 2015; Gilbert and Man 2017). Exogenous opioid exposure during pregnancy could alter functioning of opioid receptors which are linked to neurodevelopment (Byrnes and Vassoler 2018; Gonzalez-Nunez et al. 2013; Sahley and Panksepp 1987).

Exposure to opioids may also lead to increased risk for ASD indirectly through increased risk of other pregnancy complications. Women who use opioids during pregnancy are at increased risk of having children born preterm, low birth weight, and being small for gestational age, even after adjusting for confounding factors like socioeconomic status and other health conditions (Brogly et al. 2017; Norgaard et al. 2015; Whiteman et al. 2014). Poor pregnancy outcomes, like preterm birth and size for gestational age, are also

independently associated with ASD risk (Lyll et al. 2017). It is possible that any association between opioid exposure and ASD is mediated through one of these sub-optimal pregnancy outcomes.

Additionally, an association may be seen because of confounding. One type of confounding that may result in seeing an association between opioid use and child ASD is confounding by indication. A mother may be prescribed an opioid for a condition that itself is a risk factor for ASD and the association is through the condition rather than the medication (Signorello et al. 2002). For example, a pregnant woman may experience an injury that causes both pain and inflammation, and an opioid may be prescribed; however, it is the inflammation that is the risk factor for ASD rather than the opioid prescription (Meldrum et al. 2013). Outside of confounding by indication, many conditions linked to ASD are also linked to opioid use, including anxiety and depression (Rai et al. 2013; Whiteman et al. 2014), and it could be the common condition/exposure that leads to the association rather than the opioid exposure.

Current Knowledge

Across the literature, there have been few studies to assess developmental outcomes that can only be assessed after the postnatal period (Reddy et al. 2017). While longitudinal birth cohorts of opioid exposed children are being built, case-control studies can offer insight into the association between prescription opioid use during pregnancy and child ASD. Two studies were identified that assessed ASD as an outcome or maternal opioid prescription during pregnancy.

Prescription Opioid During the Pregnancy Period in the Study to Explore Early Development

In a 2019 study, Rubenstein et al. (2019) used data from the Study to Explore Early Development, a multi-site case-control study of development in preschool age children (Schendel et al. 2012). The sample was comprised of children born between 2007 and 2012 from six US states (California, Colorado, Georgia, Maryland, North

Carolina, and Pennsylvania) who were enrolled after being identified from ASD or other developmental disability service providers or from a random sampling of birth certificates. All children were screened for ASD, and those that screened positive or had past indication of ASD received a full gold-standard evaluation. Mothers answered a series of questionnaires about their environmental exposures during pregnancy, as well as providing their medical records and the child's birth record. Prescription medication, the date prescribed, and the duration of the prescription were listed on the medical records, and two independent reviewers identified the medication containing opioids.

The researchers examined prescription opioid use from 3 months pre-pregnancy to a day before childbirth, ensuring that medication was not related to childbirth or post-birth recovery. Researchers compared the odds of having an opioid prescription (ever in pregnancy, pre-pregnancy, trimester 1, trimester 2, and trimester 3 as determined by childbirth date and gestational age at childbirth) in the ASD group ($N = 1369$) to the odds of having an opioid prescription in the population comparison group ($N = 1577$). The researchers additionally evaluated whether odds of opioid prescriptions differed between a group comprised on children with developmental delay (DD) with autism symptoms ($N = 476$) and the ASD group (children with DD with ASD symptoms and children with ASD, since DD with ASD features were more phenotypically similar to the ASD group than the DD group (Wiggins et al. 2015) and to account for a sub-diagnostic autism presentation) compared to the population comparison group. For all analyses, the researchers ran an unadjusted logistic regression and an adjusted model to account for confounding due to maternal education, race/ethnicity, smoking during pregnancy, psychiatric condition during pregnancy, and year of childbirth.

In the sample 7.7% of mothers had an opioid medication prescribed during the pregnancy period. During the preconception period, mothers that were prescribed an opioid had 2.43 times the odds of having a child with ASD compared to mothers without a prescription opioid in the adjusted model (95% confidence interval, 0.99,

6.02), and there was a similar odds ratio for the DD with ASD features + ASD group (adjusted odds ratio: 2.64, 95% CI: 1.10, 6.31). Odds were also elevated for prescriptions in the third trimester (ASD adjusted odds ratio: 1.26, 95% CI: 0.94, 1.68; DD with ASD features + ASD adjusted odds ratio: 1.30, 95% CI: 0.99, 1.71), but to a lesser extent than during the preconception period. There were no associations between DD without ASD features and opioid prescriptions.

Association Between Prescription Opioid Use and Child ASD in an Israeli Health System

In 2018 Janecka and colleagues published a case-control study from the Israeli health system cohort of children born between 1997 and 2007 and followed until 2015. All children with an ASD diagnosis were sampled along with a 19.5% random sample of the original cohort (total $N = 96,270$, N with ASD = 1405). All medication types were identified through the mother's health record from 280 days before the childbirth and categorized based on drug type. The researchers ran a series of Cox proportional hazard models that varied in which covariates were included, but their confounding set consisted of maternal age, paternal age, maternal affective, anxiety, psychotic, neurologic disorders, and a number of maternal diagnoses. The researchers assessed 55 medication groups, two of which (κ and ϵ receptor agonists) were opioids.

In the sample, 1.94% of children were exposed to opioid μ receptor agonists, 1.91% to κ receptor agonists, and 1.91% to ϵ receptor agonists. In all regression models, the odds ratios were less than 1.0 when comparing odds of ASD in mothers with prescriptions to mothers without prescription; although, only the fully adjusted model assessing κ and ϵ receptor agonists met statistical significance at a 0.05 level (aOR: 0.67, 95% CI: 0.45, 0.99).

Limitations

The two described studies assess whether maternal opioid medication is associated with child ASD. Both studies had sampling methodology based on identifying ASD leading to relatively low opioid exposure. Studies derived from

cohorts of opioid users may increase power and provide further mechanistic detail into child outcomes. Additionally, both studies only assessed prescription opioids. There was no way to validate whether the medication was consumed or whether there was illicit opioid use. Further, both studies were conditioned on live birth, meaning that if opioid exposure was associated with fetal loss or still birth, we would not see that effect in these data. The Janecka study was conducted in Israel, which is not facing the same opioid epidemic as in the USA, so prescribing practice may not be directly comparable.

Future Directions

The opioid epidemic is of key concern to American policy makers and scientific agency. Of high priority are longitudinal cohort studies assessing outcomes for children exposed to opioids in utero. For example, the National Institutes of Health put out a request for applications for the “HEAL Initiative” to create a longitudinal study consortium to assess outcomes of children exposed in utero (National Institutes of Health 2018). ASD or autistic traits can be one such outcome measurement.

Additionally, large national health system data from Nordic countries should be leveraged to examine the association between prescription opioid use and child ASD, with special focus on parsing the effect of indication. Those data would be ideal because of the number of pregnant women that can be assessed and the ability to link the medical data to other data sources to better identify and control for confounding. Further, these data could be used to examine pregnancy outcomes like preterm birth and low birth weight as mediators between opioid prescription and child ASD.

While the relationship between opioid prescription in pregnancy and child ASD is not fully understood, it is important that clinicians avoid prescribing these drugs when it is not necessary and when prescribed for postoperative pain management, clinicians should be judicious in their prescribing and provide close follow-up, limited quantities, and rapid tapering (Reddy et al. 2017).

May Institute, Second Edition

Cynthia M. Anderson, Margaret Walsh and
Stephanie N Child
May Institute, Randolph, MA, USA

Definition

May Institute is a nonprofit organization. The mission of May Institute is to be the global leader in providing innovative applied behavior analytic services to individuals with autism spectrum disorder and neurobehavioral disorders across the life span. May Institute is staffed by over 2000 employees including board certified behavior analysts, special educators, and direct care professionals. Many of our staff have advanced degrees in their field of study.

Historical Background

In 1955, Dr. Jacques May and his wife, Marie Anne May, opened a small school for children with autism in Chatham, Massachusetts. They had twin boys diagnosed with autism spectrum disorder (ASD) and dedicated the school to helping their boys, and others with ASD, develop skills needed to live as independently as possible.

Today, May Institute serves individuals with ASD, brain injury, and other disabilities across the life span. We have more than 140 locations across the country including five schools, consultation

services, home-based services, vocational programs, and community-based residences for children and adults.

May Institute is invested in advancing the field of behavior analysis through high-quality research and services for people with ASD. May Institute also has played a key role in shaping policy to positively affect the lives of people with disabilities. In addition, we are passionate about training the next generation of professionals. In 2005 May Institute established the National Autism Center (NAC), which is charged with dissemination of research and training in evidence-informed practices to support individuals with ASD and other disabilities. May Institute and NAC are active centers of research and training and maintain affiliations with over 50 universities, hospitals, and human service agencies across the world. Our staff frequently publish in peer-reviewed journals and present research findings at national and international conferences. Staff have federal and private grants and contracts to support cutting edge research. In the area of training, May Institute provides training opportunities via internships and practicum placements to undergraduate and graduate students. There is a formal internship for doctoral-level psychology students that is approved by the Association of Psychology Postdoctoral and Internship Centers (APPIC).

Rationale or Underlying Theory

All clinical services and research are based on the science of behavior analysis. Applied behavior analysis (ABA) is the application of those principles to socially significant problems. There is a significant body of research documenting that interventions based on applied behavior analysis are the most effective approach for addressing the myriad difficulties that may be experienced by people with ASD and neurobehavioral disorders.

Goals and Objectives

It is the mission of May Institute to be the global leader in the provision of innovative applied

behavior analytic services to individuals with ASD and other neurobehavioral disorders across the life span. Thus, all of the services provided at May Institute use the science of behavior analysis to enhance the lives of the people served. People with ASD have deficits in communication and social interaction. For example, some individuals may struggle to communicate basic wants and needs, whereas others communicate well but have difficulty understanding subtle nonverbal communication. Other individuals might exhibit distressing repetitive behaviors and rituals or engage in stereotypic behavior that interferes with their ability to interact with others. Professionals at May Institute use evidence-based assessments and input from stakeholders to develop goals for each person that is served. Individualized, behavior analytic programs that use systematic methods of teaching are used to help people acquire meaningful and valued skills. Teaching at May Institute is positive and proactive and uses state-of-the-art technology.

Treatment Participants

May Institute provides services to children and adults with an ASD and other neurobehavioral disorders. ASD is a spectrum disorder which means that it can present in many different ways. All individuals with autism experience deficits in communication and social interaction and have struggles with restrictive or repetitive patterns of behavior, interests, or activities. However, the way in which these deficits presents can vary greatly. May Institute supports people with ASD and neurobehavioral disorders across the life span and at all levels of need. Academic, social behavioral, and vocational services are provided to individuals across the spectrum.

Treatment Procedures

The treatment procedures used by professionals at May Institute for individuals with an ASD are applied behavior analytic. The goal of all

interventions is to increase the quality of life and independence of the individuals we serve.

In our consultation services to support young children with a diagnosis of ASD, we work in both center-based programs and family's homes. We provide behavior analytic interventions designed to increase skills in social communication and interaction, as well as teaching children skills they will need to succeed in school. All interventions are individualized for a specific child and address that child's specific need. For example, some children have no means of functional communication, and intervention thus focuses on helping those children learn to communicate their wants and needs. For some children, this involves teaching spoken words; for others, we teach augmentative methods of communication, such as using picture icons on a tablet. Many children with ASD can communicate wants and needs but struggle with other aspects of communication or interaction. For example, a child may have difficulty engaging in reciprocal interaction or sharing interest in something with another person (joint attention). In such cases, intervention is directed toward enhancing those skills.

Our school consultation programs are designed to help teachers and other educational professionals develop and enhance skills to support students with ASD. Activities include workshops and training, classroom-based consultation, and direct work with students and teachers. In addition, May Institute operates "model classrooms" through which we help districts train educators to implement state-of-the-art behavior analytic interventions to support students.

May Institute operates five private schools, four support students with ASD and one supports students with brain injury. Across schools, our students each have an Individualized Education Plan (IEP) specifying goals in education (e.g., reading), acquisition of communication and interaction (e.g., increasing peer interactions), and addressing any behavioral challenges (e.g., replacing self-injury with more desirable behavior). All programming is based on principles of behavior analysis, including the way academic instruction is provided, how skills are taught,

how challenging behavior is addressed, and how vocational skills are taught.

For academic instruction, teachers design individualized education plans based on comprehensive assessments of students needs and provide academic instruction using evidence-based methods of instruction in both group and individualized instruction. In addition, May staff utilize behavior analytic assessments and intervention strategies to help each student learn to communicate wants and needs, to initiate and carry on conversations, and to interact with peers and adults in a developmentally appropriate manner. A goal of interventions in this area is to teach in such a way as facilitate independence and generalization to the community. Behavioral challenges are addressed in a comprehensive manner that always begins with a functional behavior assessment (FBA) to identify what evokes the behavior (e.g., requests) and what seems to maintain or reinforce the behavior, such as avoiding instruction, gaining attention from others, or getting access to some preferred activity or item. Results of the FBA are used to develop an intervention that consists of strategies to (a) reduce the likelihood the behavior will occur in the first place, (b) teach new skills, (c) increase the occurrence of desired behavior, and (d) decrease the likelihood of challenging behavior. Vocational and prevocational skills are also taught across the schools utilizing the principles of behavior analysis. Two of our five schools offer community-based residential services. Residential staff members utilize behavior analytic interventions to teach skills ranging from self-care (e.g., tooth brushing) to daily living skills (e.g., meal preparation) with the goal of increase the students' independence and increase their quality of life. Clinicians and educators place an emphasis on involving family members into the educational and treatment process and systematically plan for generalization of acquired skills across various environments.

Adult services provided at May Institute include day programs, shared-living, and community-based residential programs. The primary goal of adult services is to provide individualized supports that are evidence-based. We

serve adults living with ASD, intellectual disabilities, and traumatic brain injury at all stages of their adult lives. We provide a wide range of services that include day programs, shared-living, community-based residential programs, and independent living programs. The services provided to adults focus on teaching skills that increase independence in all areas of their lives. Most of the adults we serve have an Individualized Support Plan (ISP) that is developed by a team of people who are familiar with the individuals' desires and support needs. The ISP specifies the person's vision for their life and the goals they want to work on to achieve their vision. It also identifies the kinds of support the individual will need to meet their goals and live in the least restrictive environment possible. Trained support staff help the adults in our care participate meaningfully in their communities, develop social skills needed to form and maintain relationships, and learn skills that increase their ability to participate fully in daily routines throughout their lives.

Efficacy Information

Interventions based on the science of behavior analysis have repeatedly been demonstrated to be highly effective in addressing the challenges experienced by people with ASD (e.g., Heyvaert et al. 2014; National Autism Center 2015; Odom et al. 2010; Smith and Iadarola 2015; Wong et al. 2015). For example, both NAC and Wong et al. reviewed peer-reviewed intervention studies for individuals with ASD to identify practices with a strong evidence base. Wong et al. restricted the sample to ages birth to 22, whereas NAC examined studies across the life span. Both identified broad categories of practice (e.g., prompting, reinforcement), and there was significant overlap between the two reviews. All evidence-informed practices were, in the words of Wong et al., "...fundamental applied behavior analysis techniques..." (p. 1957). At May Institute, all interventions used fall within the evidence-informed categories identified in the above-referenced reviews.

Outcome Measurement

At May Institute, our staff collect data on all identified goals and target behaviors of the individuals we serve. For example, if a treatment goal is increasing functional communication, staff might record the frequency of targeted communicative responses (e.g., signing, "apple"). If a goal is increasing reading fluency, staff might measure words read correctly per minute to monitor acquisition of reading. When a goal is addressing challenging behavior, staff record the frequency of challenging behavior and also the occurrence of more desired behavior. In addition to recording outcome measures, staff also collect data on treatment integrity, to monitor the fidelity with which programs and interventions are implemented as designed. If outcome data suggest an intervention is not producing desired goals and treatment integrity is good, then the intervention would be adjusted to produce desired outcomes. Alternatively, if treatment integrity was low, additional training would be provided to help staff implement the intervention as designed.

M

Qualifications of Treatment Providers

All treatment providers at May Institute are appropriately qualified and credentialed for their given profession and area of expertise. For example, staff include licensed psychologists and licensed behavior analysts as well as certified teachers, licensed or certified speech and language therapists, occupational therapists, and social workers.

[Typical length](#)

Definition

Mean length of utterance (MLU) is the average number of morphemes per utterance. It is an index of expressive language development used beyond the stage of single words, when a child uses two or more words together in an utterance. It is calculated in 100 spontaneous utterances by counting the number of morphemes in each utterance divided by the total number of utterances. MLU is used as a benchmark to assess individual differences and developmental changes in grammatical development in children in the early stages of language acquisition. Children with autism frequently demonstrate differences in MLU compared to non-autistic developmentally delayed children and typically developing children by producing shorter utterances with fewer grammatical morphemes. Recent research has acknowledged the use and utility of using MLU as an index for language development in children with autism (Condouris et al. 2003; Tager-Flusberg et al. 2009).

The use of MLU as a standard for measuring children’s language development was initially described in 1973 when spontaneous language transcription and morpheme analysis methods were codified and subsequent stages of expressive language development were identified (Brown 1973). Table 1 contains the six stages identified

Mean Length of Utterance (MLU), Table 1 Brown’s stages of language development by mean length of utterance

Stage	MLU	Age	Linguistic characteristics
I.	1.0–2.0	12–26 months	Single-word and two-word utterances that express early semantic relationships, such as action-object and action-location
II.	2.0–2.5	27–30 months	Emergence of grammatical inflections, such as present progressive tense - <i>ing</i>

(continued)

Mean Length of Utterance (MLU), Table 1
(continued)

Stage	MLU	Age	Linguistic characteristics
III.	2.5–3.0	31–34 months	Development of sentence types including declarative, interrogative, negative, imperatives
IV.	3.0–3.75	35–40 months	Emergence of sentence coordination using early conjunctions, such as <i>and</i> , <i>because</i>
V.	3.75–4.5	41–46 months	Continued development of complex sentences including coordination, complementation, and relativization
VI.	4.5 +	47+ months	Continued refinement

by Brown (1973), the corresponding MLU, and the linguistic characteristics of each stage.

Measles and Autism

Paul A. Offit
Division of Infectious Diseases, Department of Pediatrics, The Children’s Hospital of Philadelphia, Philadelphia, PA, USA

Birth of a Hypothesis

In 1998, Andrew Wakefield, a British surgeon, published a case series in the *Lancet* of eight children with autistic spectrum disorder; all had received the combination measles-mumps-rubella vaccine and all had lymphonodular hyperplasia of the small intestine. This study gave birth to the notion that MMR vaccine caused autism. To avoid autism, Wakefield suggested that the three vaccines in MMR vaccine should be given separately. The hypothesis that MMR caused autism was subsequently rejected by epidemiological studies (see section titled “MMR and Autism”).

Wakefield’s hypothesis that MMR vaccine caused autism was rooted in his studies examining the relationship between wild-type measles virus infections and inflammatory bowel disease. These studies set the stage for his notion that measles virus – either wild-type virus or attenuated virus – could cause intestinal disease. Using a monoclonal antibody, Wakefield and coworkers detected measles virus nucleoprotein in biopsy specimens from patients with Crohn’s disease. However, this monoclonal antibody was subsequently found to detect a host, not measles virus, protein and bound to intestinal tissues obtained from patients with or

without inflammatory bowel disease (IBD). Studies detecting measles virus genome by polymerase chain reaction also failed to detect measles virus in patients with IBD.

Wakefield's claim that autism could be avoided by separating the MMR vaccine into its three component parts was also born of studies of wild-type measles virus. Wakefield and coworkers performed a study of children born in England during a 1-week period in 1970 by evaluating the relationship between the timing of childhood infections and IBD. Wakefield observed an increased risk for IBD in children who were infected with measles and mumps virus within the same year. However, this study was limited in that (1) few patients were studied and (2) histories of infection were obtained 4–10 years after the event raising the question of recall bias.

Wakefield later stated that his claims that wild-type measles virus caused IBD were incorrect.

Measles-Mumps-Rubella (MMR) Vaccination

Paul A. Offit

Division of Infectious Diseases, Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Definition

In 1998, Dr. Andrew Wakefield and coworkers at the Royal Free Hospital in London published a paper in *The Lancet* titled "Ileal-lymphoid-nodular hyperplasia, non-specific colitis, and pervasive developmental disorder in children." The paper detailed the stories of eight children: all had recently received the combination measles-mumps-rubella (MMR) vaccine and then developed signs and symptoms of autism spectrum disorder. By endoscopy, these researchers also found evidence for lymphoid hyperplasia in Peyer's patches of the small intestine. Wakefield and his coworkers reasoned that the measles

vaccine component of MMR was traveling to the intestine, inducing intestinal disease, and allowing for entrance of encephalopathic proteins that traveled to the brain and caused autism.

Media coverage from this paper caused many parents to withhold MMR vaccine for their children. As a consequence, hundreds of children developed measles in England, the United Kingdom, and Ireland, and four children died of complications from the disease. In the United States, parents of 125,000 children withheld the MMR vaccine accounting, in part, for a measles epidemic in 2008 that was larger than any in more than a decade.

The academic and public health communities in several countries responded by examining retrospectively children who either had or had not received MMR vaccine to determine whether autism was associated with vaccination. The results were clear, consistent, and reproducible. MMR vaccine was not associated with autism. Further, the physiological basis of Wakefield's contention was refuted when other researchers were unable to identify persistent measles vaccine virus genome in autistic children more frequently than in non-autistic children. Nor were the encephalopathic proteins posited by Wakefield ever identified.

Measure

► Criterion

Measurement Error

Haleigh M. Scott¹ and Susan M. Haverkamp²

¹Department of Disability and Human Development, University of Illinois at Chicago, Chicago, IL, USA

²Nisonger Center, UCEDD, The Ohio State University, Columbus, OH, USA

Synonyms

Bias; Error of measurement; Standard error of measurement

Definition

Measurement error is a statistical term that refers to the difference between the obtained value or score and the hypothetical “true” value. Psychological tests rarely, if ever, provide a perfect measure of a construct. The degree of uncertainty or

variability surrounding the obtained value is referred to as measurement error. Measurement error can be divided into two parts: random error and systematic error. Random errors are statistical fluctuations (in either direction) in the measured data due to precision limitations of the measurement device. Random errors usually result from the experimenter's inability to take the same measurement in exactly the same way. Random error is variation due to a wide variety of uncontrollable and unpredictable factors and cannot be eliminated within a study or a test.

Systematic error, also called "bias," may occur in the sampling stage of an experiment as when the sample obtained differs systematically from the target sample. Systematic error can also occur at the pre-measurement, measurement, or calculation stage of an experiment as when an instrument is not used as the manual prescribes or when observer-expectancy or subject-expectancy effects are allowed. Systematic error can include discrepancies in measurement tools, observational bias, or shared environment effects. Systematic errors apply universally across the sample and are referred to as "bias" in social science research. Though difficult to prevent, systematic error can be eliminated once identified. Bias in sampling, measurement, or calculation can be corrected statistically.

Measurement error is negatively correlated with reliability. According to classical test theory, reliability is the proportion of true score to obtained score. The higher the reliability coefficient of a test, the more confidence can be had in making interpretations about any individual test score.

IQ testing, often part of the diagnostic procedure for ASD and other developmental disabilities, provides a good illustration of measurement error. Measurement error, the discrepancy between the obtained score and the true score on a test, results from both random and systematic error. If the same person was to take the same IQ test three separate times, they may well receive three different scores. Their scores would cluster around their "true" IQ score. This is the result of random error such as sometimes guessing correctly and sometimes incorrectly. A certain

amount of random error is unavoidable in measuring any construct, including IQ. Test developers have taken care to limit systematic errors that may result from inconsistent administration of the test by carefully describing administration procedures. IQ test developers have also been diligent in minimizing systematic errors that may bias the test according to gender, cultural, racial, and ethnic differences.

Measuring Language Change Through Natural Language Samples

Mihaela Barokova

Center for Autism Research Excellence, Boston University, Boston, MA, USA

Synonyms

[Language outcome measures](#)

Definition

Assessing changes in expressive language ability by analyzing recordings of speech from typical, everyday situations.

Expressive language is integral to social communication and plays a central role in development. Its emergence is one of the strongest predictors of positive long-term outcomes in ASD (Howlin et al. 2004), which is why it has become

the target of many interventions (Kasari et al. 2010). However, widely used methods for characterizing language ability in ASD, like parent questionnaires and standardized tests, are often not fit to detect changes in expressive language resulting from treatments and interventions.

In contrast, natural language samples, which are audio and/or video recordings of spontaneous speech, can be a useful tool for measuring language change in ASD (Barokova and Tager-Flusberg 2018). They can be collected in different contexts (e.g., free play, reading a book, specific activity) by different people (e.g., parent, peer, teacher, researcher) in a variety of settings (e.g., home, school, lab) ensuring the samples are representative of the speaker's everyday language use. A single sample can be coded at the level of the sounds, words, sentences, or appropriate use in context, thus providing a comprehensive picture of the speaker's ability. This is especially useful considering language is one of the most heterogeneous characteristics in ASD (Tager-Flusberg et al. 2009). Measures derived from natural language samples (e.g., frequency of utterances, number of different words used) can be sensitive to subtle changes in language ability that could go undetected if parent questionnaires or standardized tests are used instead. Furthermore, other measures derived from the samples, like number of different topics discussed and amount of echolalia, can serve as proxy for restricted interests and repetitive behaviors, thus capturing change in core autism symptoms beyond social communication.

There are no practice effects associated with the elicitation of natural language samples, so they can be collected pre- and post-intervention, and a similar elicitation procedure can be used with individuals from a wide range of age and language ability, who often comprise the participant pool of ASD intervention and treatment studies.

There are ongoing efforts in the field of ASD and other neurodevelopmental disorders to design standard elicitation protocols for natural language samples (e.g., Berry-Kravis et al. 2013) and determine which measures derived from them have the most sound psychometric properties to detect change in language ability and core symptoms. This is a

necessary step before the wide implementation of these measures as measures of change in treatment and intervention studies.

MECP2 Gene

Kartik Pattabiraman
Child Study Center, Yale School of Medicine,
New Haven, CT, USA
Department of Psychiatry, Yale School of
Medicine, New Haven, CT, USA

Synonyms

[Methyl CpG-binding protein 2](#)

Definition

MECP2 is the primary gene implicated in Rett Syndrome, a neurodevelopmental disorder that primarily affects females. *MECP2* is a gene located on the X chromosome that encodes the protein Methyl CpG-binding protein 2 (MECP2). Inactivation of a single copy of *MECP2* leads to impaired language, social skills, and motor coordination, as well as scoliosis, dysregulated breathing, and seizures in females. Deletion of both copies of *MECP2* in mice mimics the symptoms of Rett Syndrome. Duplication in *MECP2* gene has been implicated in severe male intellectual disability–associated premature death. *MECP2* is expressed throughout the body with strongest expression in neurons. *MECP2* functions as a transcriptional repressor, thus turning off expression of other genes.

Medial Temporal Lobe

Avery Voos¹ and Alexander Westphal²

¹Yale Child Study Center, New Haven, CT, USA

²Division of Law and Psychiatry, Yale Child Study Center, Yale School of Medicine, New Haven, CT, USA

Synonyms

[MTL](#)

Definition

The medial temporal lobe (MTL) is a region within the cerebral cortex comprised of a system of anatomically related structures, including the hippocampal region and the adjacent entorhinal, perirhinal, and parahippocampal cortices. This system is involved in the creation of declarative memory (see Squire, 1991 and 2004 for a review) and also in the regulation of emotional reactions. The MTL has been discussed as one of the candidate neural substrates underlying the social deficits in autism. Evidence from monkey studies demonstrates that neonatal lesions to the MTL result in persistent socioemotional abnormalities later in life. Additionally, declarative memory seems to be affected in high-functioning individuals with ASD who were found to have deficits in episodic memory, with relatively intact semantic memory. Postmortem investigation of the brain in eight individuals with autism also revealed microscopic cytoarchitectonic abnormalities (increased cell density and small cell size) in MTL structures.

Medicaid and Autism Spectrum Disorder

Policy and Analytics Center, A.J. Drexel Autism
Institute, Drexel University, Philadelphia, PA,
USA

Definition

Medicaid is a healthcare program in the United States (US) that covers over 65 million Americans (Centers for Medicare and Medicaid Services 2019). In addition to providing coverage for healthcare services for low-income individuals, pregnant women, and children, Medicaid is a critical support for individuals with disabilities including physical disabilities, intellectual and developmental disabilities (IDD), and autism spectrum disorder (ASD)

(Centers for Medicare and Medicaid Services 2019; Mark et al. 2003; Shattuck et al. 2009; Shea et al. 2018; Vladeck 2003; Wang et al. 2013). Since Medicaid is among the only insurance programs available in the USA for transitioning youth with disabilities, more than ten million adults and children with disabilities are enrolled in Medicaid on the basis of their disability including those with ASD (Medicaid and CHIP Payment and Access Commission (MACPAC) 2017).

Historical Background

Medicaid emerged in US healthcare policy in 1965 as Title XIX of the Social Security Act during the Lyndon B. Johnson administration and has, over the past six decades, been a key payer for services for individuals with disabilities including ASD (Centers for Medicare and Medicaid Services 2015). Early Periodic Screening, Diagnosis, and Treatment (EPSDT) was established in 1967, for example, and provides a comprehensive suite of medically necessary services for all Medicaid-enrolled children through age 20 (English 1993; Wirth and Gabor 2016). EPSDT, depending on the state, pays for ASD screening, diagnosis, and evidence-based treatments like applied behavior analysis (ABA) (Autism Speaks 2017; Wirth and Gabor 2016).

Additionally, Medicaid 1915(c) home- and community-based services (HCBS) waivers, created in 1981, allow individuals with disabilities to receive services in their homes and communities as opposed to institutional settings like nursing homes, hospitals, or state centers (Braddock et al. 2011; Centers for Medicare and Medicaid Services 2015; Ng et al. 2012; Rizzolo et al. 2013). Through HCBS waivers, individuals can receive an array of services and supports such as habilitation, employment supports, respite care, transportation, behavior supports, and community support (Braddock et al. 2011). HCBS waivers vary in availability across the lifespan or specifically for children with ASD and are typically capped in enrollment or have limits on amounts

of services that can be provided. However, HCBS waivers are especially critical for adults with ASD after they are no longer able to access entitlement-based services and supports through the education system and EPSDT (Koffler Miller et al. 2017; Rizzolo et al. 2013; Shattuck et al. 2012).

Current Knowledge

There has been increasing attention to the use of Medicaid-funded services by individuals with ASD of all ages as this population grows, as it is among the only insurers available across the lifespan.

Several studies (Semansky et al. 2011; Shattuck et al. 2009; Shea et al. 2018; Wang and Leslie 2010) have explored the prevalence of individuals with ASD enrolled in the Medicaid system, by state and nationally, and have observed increasing use of Medicaid among individuals on the spectrum over time (Semansky et al. 2011). Exploring the use of Medicaid among the ASD population has yielded a tremendous amount of knowledge about the changing clinical, policy, and services landscape including average age of diagnosis as it differs by race/ethnicity (Mandell et al. 2002), expenditures and societal costs (Cidav et al. 2013; Mandell et al. 2006), program experiences and provider training needs (Koffler Miller et al. 2017), and unwanted outcomes, such as hospitalization (Mandell et al. 2012; Turcotte et al. 2018).

Analyzing Medicaid data in studies allows researchers to observe patterns in service use, expenditures, inpatient versus outpatient service utilization, and medication usage and see how that changes over time as individuals age. A study using national Medicaid data from all states, including Washington, D.C., found that as individuals with ASD are aging into adulthood, they are increasingly reliant on publicly funded services through Medicaid (both psychiatric and medical) and the expenditures for those services are also increasing (Shea et al. 2018). This knowledge helps researchers and policymakers alike to understand the changing needs of this growing population.

Future Directions

Because it has become a primary payer for behavioral health, HCBS, and other services that are necessary for many individuals with ASD (Centers for Medicare and Medicaid Services (CMS) 2017; Koffler Miller et al. 2017) and does not rely on employment for eligibility and coverage (Croen et al. 2014; Koffler Miller et al. 2017), Medicaid is an integral support system for individuals with ASD across the lifespan in the USA. As such, it is critical that researchers focus their efforts on understanding the interplay between ASD and Medicaid through service utilization and expenditures and the changes in service access across the lifespan.

Medical Conditions Associated with Autism

Jessica L. Roesser

Department of Pediatrics (SMD), University of Rochester, School of Medicine and Dentistry, Rochester, NY, USA

Genetic disorders; Nutritional issues; Pica; Seizures; Sleep disorders

Background

Children with autism spectrum disorders (ASD) including autism, Asperger's syndrome, and pervasive developmental disorder, not otherwise specified, have similar medical problems as children without disabilities. These children can have colds or ear infections as well as other typical illnesses of childhood and adolescence. Little research has addressed the medical problems of adults with autism. The primary care provider should monitor the health of individuals with ASD in the “medical home.” The medical home

describes a source of primary care that is accessible, continuous, culturally sensitive, and providing coordinated care. A recent report indicated that children with autism spectrum disorders were less likely than children with other special needs to receive their care in a medical home (Brachlow et al. 2007). This leads to more financial needs for the parents and more problems with access to care (Kogan et al. 2008). In addition to routine and disorder-specific anticipatory guidance, individuals with ASD need to be monitored for medical conditions for which they may be at higher risk including seizures, genetic abnormalities, sleep disorders, disordered eating/nutritional issues, pica, and GI issues.

Seizures

Seizures develop in approximately 10–25% of children with autism (Myers et al. 2007). There is no one type of seizure that is more common than other seizure types. Children with ASD can have absence seizures (staring spells), tonic-clonic seizures (grand mal seizures), myoclonic jerks, atonic seizures (drop attacks), or partial seizures (movements without loss of consciousness). The first peak time for onset of seizures in children with ASD is between 1 and 5 years of age. The second peak occurs in adolescence between 12 and 18 years of age (Myers et al. 2007). The anticonvulsant medications used for other individuals with seizures are used to treat seizures in individuals with ASD.

Landau–Kleffner syndrome is a seizure disorder that may be considered in the differential diagnosis of ASD. This rare type of seizure has a characteristic EEG pattern and can cause a regression in language or aphasia (Kliegman et al. 2007). Landau–Kleffner syndrome is more common in boys, with regression in language and seizure onset in previously socially typical children at around age 5. This regression occurs later than that typically seen in ASD. Some of the behaviors can be similar to those seen in children with ASD including agitation, poor attention span, and irritability. In 70% of the children with Landau–Kleffner syndrome, there is another

seizure type. Obsession and insistence on routine are not typically seen. Anticonvulsant medication may improve symptoms in Landau–Kleffner syndrome. Anticonvulsant medication may be useful for agitation or other behaviors in children with ASD in addition to seizure control, but it does not improve language.

In general, seizures are not a sensitive predictor of outcome in children with ASD. However, the prevalence of seizures is higher among individuals with moderate to severe intellectual disability and those with motor deficits. In children with severe intellectual disability and ASD, seizures may occur in up to 42%. In children without intellectual disability, etiologic or genetic diagnosis, or family history of epilepsy, the rate is only 6–8%. Individuals with autism plus epilepsy have on the average lower IQs and poorer adaptive, behavioral, and social outcomes than those without epilepsy. There are also higher rates of abnormalities on electroencephalography (EEG) without clinical seizures among people with ASD. The rate may be as high as 10–72%. The medical literature has not demonstrated benefit to treating these electroencephalographic abnormalities. There is currently not enough evidence to suggest routine screening EEGs without history or clinical evidence of seizures. Since the rate of seizures is higher in children with ASD, EEG should be considered whenever there are symptoms consistent with seizures (Myers et al. 2007).

Genetic Abnormalities

There is a 60–90% concordance rate of ASD in identical twins, which means that most of the time identical twins both have ASD. In fraternal twins, there is only a 30% concordance rate (Kliegman et al. 2007). Recent studies support that a strong genetic predisposition to autism is genetic, although there is a significant environmental impact as well.

No consistent genetic abnormalities are found in individuals with ASD, although the overall prevalence of genetic abnormalities on testing may be as high as 20%. The rate of fragile X is reported to be 0.045%, and the rate of abnormality

on karyotype (or evaluation of the structure of stained chromosomes by microscopy) is 5% or less (Miller et al. 2010). A new genetic test called chromosomal microarray (CGH) compares the units of DNA in an individual to the composite normal to identify duplications (gain of material) or deletions (loss of material). Abnormalities on CGH microarray are seen in approximately 17–20% of the children with autism spectrum disorders who complete this testing (Shen et al. 2010). Not all of the abnormalities found on CGH microarray in individuals with ASD are associated with or cause autistic symptoms. In the most thorough and recent study, 9% of CGH abnormalities were considered abnormal or likely to be causative of the autism symptoms. Children with dysmorphic (or unusual) features and those with lower cognitive skills are more likely to have abnormalities on genetic testing. Newer genetic testing includes whole exome sequencing to look for regions with increased recessive genes. Nineteen genes have been identified as candidate genes for causing ASD through this new testing. The whole exome sequencing leads to a syndromic diagnosis for 12–15% of children with ASD (Tamimi et al. 2015).

Specific syndromes associated with ASD include X-linked intellectual disability, tuberous sclerosis, and Angelman syndrome, among other disorders. Fragile X is the most common inherited cause of intellectual disability. These children have intellectual disability, macrocephaly, large pinnae, hypotonia, and joint laxity (Johnson et al. 2007). Roughly 20% of the children with fragile X also have ASD symptoms (Hatton et al. 2006). However, only 0.045% of children with ASD have fragile X (Shen et al. 2010). Children with tuberous sclerosis have hypopigmented skin areas, have brain and skin tumors (CNS hamartomas and fibroangiomata), are at a high risk for seizures, and have ADHD or autistic-like behaviors. Angelman syndrome is characterized by global developmental delays especially with language, a wide-based ataxic gait, and progressive spasticity with a particularly jovial personality. This is caused by various genetic abnormalities of chromosome 15 q11–13. Females with symptoms of ASD should be

considered for Rett syndrome caused by the MeCP2 gene. Midline hand-wringing or patting behaviors will typically distinguish these children from those with ASD alone.

Sleep Disorders

Sleep problems are very common in children with autism spectrum disorders and can occur throughout childhood and adolescence. The sleep disorders are variable and can include difficulty settling to sleep, early rising, night waking, sleepwalking, or night terrors. The lack of sleep can affect daytime functioning including behaviors, cognitive skills, and memory. Frequent sleep problems greatly affect family stress and functioning.

Sometimes, there is a medical cause for the sleep problems such as gastroesophageal reflux, obstructive sleep apnea, or nutritional deficiency (e.g., decreased iron stores associated with restless legs syndrome). Children with GERD or gastroesophageal reflux disease can have some vomiting or discomfort during the night from stomach acid refluxing into the esophagus. Obstructive sleep apnea is a respiratory problem during sleep where the airway does not remain patent. This causes the person to awaken. With the interrupted sleep, children can be inattentive or agitated during the day (Myers et al. 2007).

The medical literature does not contain data at this time regarding the frequency of medical causes for sleep difficulties in people with ASD. History and physical exam are used to determine the need to perform a medical workup for causes of sleep problems. In most children, behavioral measures are used to treat the sleep problems. Behavioral measures can include setting up a bedtime routine. Medications sometimes used include melatonin, alpha-adrenergic agonists (such as clonidine and guanfacine), and antihistamines (such as diphenhydramine). Further research needs to be done on the causes of sleep difficulties in people with ASD as well as effective treatments.

GI Issues

The prevalence of GI issues in children with autism spectrum disorders varies from 9% to 72%. The most common problems are chronic

constipation or chronic diarrhea. One reason for the difficulty in assessing this problem is the communication difficulty children with ASD often have. Many children are nonverbal, and many of those who can communicate have difficulty with describing subjective feelings or isolating a source of pain. Some children will not have identifiable symptoms relative to the GI tract but instead will have behavioral changes or changes in sleep patterns as evidence of GI issues. Careful evaluation including full physical exam and medical history are indicated anytime there are major changes in the behavior of an individual with ASD.

The common GI problems that are seen in other people can also be seen in people with ASD. An individual with constipation might have hard infrequent stools or might stool daily with distress. They might also have behavioral problems that are only clarified when physical exam palpation stool or an X-ray identifies significant constipation. Treatment might include a bowel regimen. Chronic diarrhea is also reported in people with ASD. The same etiologic workup entertained for other patients should be performed. Abdominal discomfort may be due to common problems such as lactose intolerance or less frequent medical disorders such as celiac disease. History and physical exam are important sources of information to the clinician in determining initial workup and appropriate referral to a gastroenterologist.

The evidence for autistic enterocolitis (leaky gut) is limited at this time. The evaluation of children with ASD and GI symptoms found no difference in enzyme activity, intestinal permeability, or inflammation compared to typically developing children (Kushak et al. 2016). Prospective studies need to be done on the causes and treatments of the GI symptoms reported in individuals with ASD.

Nutritional Deficiencies

Food aversions are commonly reported in children and youth with ASD. In addition to self-restriction, dietary restriction for therapeutic reasons might occur.

The gluten-free and casein-free diet is a popular dietary treatment for the symptoms of autism.

This involves removing all foods that contain gluten from wheat, barley, and rye and casein, found in milk products. This diet may impact protein quality of food consumed (Arnold et al. 2003). It also requires provision of an alternate source of calcium and vitamin D than dairy products.

Children with ASD who have a limited food repertoire are at risk for consumption of an inadequate diet (Bandini et al. 2010). Many children with ASD are supplemented with vitamins, but this can lead to excess in some vitamins. (Stewart et al. 2015) The impact of a limited diet on long-term health requires further study.

Pica

Pica is the ingestion and mouthing of nonfood objects. Chewing or mouthing toys and things in the environment is typical in children less than 12 months of age. Pica can persist because of sensory reasons, delay to a younger developmental level, and anxiety and may be due to nutritional deficiencies such as iron deficiency. Pica can also lead to increased lead levels from ingestion of lead dust in the environment or items manufactured with lead. It is advisable to continue monitoring lead levels in children who continue to have pica beyond the toddler stage when monitoring typically occurs (Myers et al. 2007).

Pathophysiology

There are a number of medical conditions associated with autism spectrum disorders (ASD). Except for some genetic and neurologic abnormalities, medical conditions associated with ASD are not responsible for the symptoms of autism. Discomfort and medical illness can exacerbate behavioral symptoms. Medical and dental causes of new-onset behaviors should be considered.

Hypotheses have been generated associating GI pathology such as leaky gut or increased permeability with symptoms of ASD. More recent studies have not confirmed this association; however, the potential for disorders affecting the brain and gut requires further study. There is no specific

pathology identified to cause the constipation, diarrhea, or abdominal pain reported in children with ASD. Lymphonodular hyperplasia (lymph nodes in the intestine) may be a normal variant. Investigators are pursuing the possibility of immunologic differences in the intestine in children with ASD.

The etiology of the sleep difficulties of children and youth with ASD may be related to abnormal melatonin metabolism, atypical sleep architecture, restless legs syndrome, or behavioral sleep disorders. Etiologic and therapeutic studies are ongoing to address sleep in individuals with ASD.

Medical Education on Autism

Golnaz Ghaderi¹ and Kelly D. Coons-Harding²

¹Department of Social Sciences, University of Ottawa, Ottawa, ON, Canada

²Department of Psychology, Laurentian University, Sudbury, ON, Canada

Historical Background

Research shows that medical practitioners, including family physicians and pediatricians, are often the first healthcare professionals whom families of individuals with a suspected diagnosis of ASD are referred to in order to receive a diagnosis and/or to receive treatment (Self et al. 2015). Nonetheless, families of individuals with ASDs have raised concerns about the diagnostic and treatment processes of ASDs. Families of individuals with ASDs often feel unsupported because of medical practitioners' lack of knowledge and competency around the diagnosis and treatment of ASDs, misdiagnosis with other disabilities (e.g., attention deficit hyperactivity disorder), as well as multiple referrals (Brookman-Frazee et al. 2012; Glazzard and Overall 2012). Furthermore, research investigating the experiences of medical practitioners providing care for individuals with ASDs have revealed that many providers lack expertise about the diagnosis of, or the identification of, ASDs (Brookman-Frazee et al. 2012; Dosreis et al. 2006). Additionally, medical professionals often report that they do not receive ASD-specific education and training during medical school (Finke et al. 2010), and many medical

practitioners feel unskilled when providing care for individuals with ASD (Crais et al. 2014).

Current Knowledge

Despite medical professionals reporting that they often feel unprepared to address ASDs in primary care, relatively little is known about the actual content within medical education regarding ASD and developmental disabilities. Medical practitioners often attribute their lack of preparedness regarding the diagnosis and treatment of ASDs to the lack of education and training they receive during their undergraduate medical education (Carbone et al. 2010; Daniels et al. 2014; Rhoades et al. 2007). It is important to note that formal medical education differs widely across countries, provinces or states, and even medical schools. Therefore, there is a lack of consistency within medical education when it comes to formal training about ASDs. While some medical professionals may feel prepared to work with individuals with ASD and their families, other providers may report that they have had no experience or education about ASD.

By way of example, many pediatricians have reported a lack of ASD-specific education and training during medical school (Finke et al. 2010). Additionally, some of the physicians (i.e., family physicians, pediatricians, developmental pediatricians, and psychiatrists) in Ontario, Canada, have indicated that they may have received only one lecture regarding ASD during their undergraduate medical education and that they often had to educate themselves through attending conferences, workshops, and trainings (Ghaderi and Watson in review). Nonetheless, medical students who have received hands-on and in vivo experience working with individuals with ASDs during their medical education have reported higher levels of knowledge, comfort, as well as more positive attitudes toward working with this population compared to students who have not received such trainings (Havercamp et al. 2016). There is a lack of existing research and poor training (e.g., limited and not very efficient). Consequently, medical providers are often ill-prepared to address the needs of their patients with ASDs.

Future Directions

Given medical practitioners' concerns regarding the lack of education and training on ASD during medical education, it is imperative for future research to investigate the current medical education and the curriculum content on ASDs specifically. There is a demonstrated need for increased exposure to consistent, formalized education on ASD within the medical field.

Some future research and practice recommendations include:

1. The promotion of further ASD-specific education and training in medical schools that includes formal education on key issues regarding the prevalence, identification, diagnosis, and treatment of ASDs. It is possible that students currently do not have an interest in these topics and greater exposure to individuals with ASDs, and other developmental disabilities, may increase their awareness and interest in working in this field.
2. The integration of clinical and hands-on working experiences with the ASD population is important. Employing teaching strategies that include a combination of didactic teaching, small-group discussions, and case studies would improve medical students' knowledge regarding the specific needs of individuals with ASDs as they transition into medical practice.
3. There is a need for further formal education and training opportunities that include experiential learning. Additionally, medical learners may also benefit from lectures or discussions delivered by individuals with ASDs and lived experiences, as well as educational sessions paired with standardized patient encounters in order to improve their knowledge regarding the diagnosis and treatment of ASDs.
4. Given the large number of topics learners must cover in their medical education, students should also feel prepared and be encouraged to add to their own education and acquire information from informed and reliable sources, when necessary. Learners should be encouraged to engage in individual learning opportunities about ASDs and other developmental disabilities.

Medical Evaluation in Autism

Jessica L. Roesser

Department of Pediatrics (SMD), University of Rochester, School of Medicine and Dentistry, Rochester, NY, USA

Definition

All children diagnosed with an autism spectrum disorder should have an evaluation by a medical professional to consider the potential causes of developmental disability and evaluate the individual for common co-occurring medical conditions. The medical evaluation includes a thorough medical history including family history, physical examination, and neurological examination. Consideration of genetic causes requires laboratory testing most commonly using chromosomal

microarray if no specific syndrome requires workup. Other genetic screening tests might include testing for X-linked intellectual disability, Rett syndrome, or other diagnoses suggested by the history and physical examination.

Historical Background

In 1941, Dr. Leo Kanner first described autism as a discrete disorder. Around the same time, Dr. Hans Asperger identified a similar disorder in Germany. While a similarity to childhood schizophrenia led many to consider autism a psychiatric disorder, Dr. Bruno Bettelheim in the 1950s attributed it to cold parenting. In the 1960s, Dr. Bernard Rimland proposed that there was a biologic basis for autism. This led the way to thinking about medical evaluation for etiology of ASD. The capacity to karyotype and see genetic abnormalities in the chromosomes associated with disease states was developed in the 1960s. This advance permitted the identification of the chromosomal abnormalities responsible for genetic syndromes. Chromosome analysis was not routinely done on children with developmental differences until 1966. The biggest breakthrough in etiologic evaluation of developmental disability occurred when phenylketonuria or PKU was identified as a metabolic problem that could cause intellectual disability and autism. This disorder resulted in ASD in 20% of untreated cases. Now, with newborn screening, it is a preventable cause of ASD. It is routine for babies in the USA to be screened for PKU and other metabolic disorders. Prenatal infections need to be considered in the etiology of ASD. Prior to the introduction of the rubella vaccine, congenital rubella was a cause of autism that has now been all but eliminated.

Advances in neuroimaging allow for investigation of central nervous system anomalies when indicated by history and physical examination.

Current Knowledge

The current recommendation for evaluation of children diagnosed with autism spectrum

disorders is to start with a thorough history and physical exam. The clinician should obtain a three-generation genetic family history and full history including past medical history, developmental history, and behavioral history. The history often guides the rest of the evaluation. All children with language delays should have a hearing evaluation. In children who are school age and verbal, school-based hearing screening may suffice (Myers et al. 2007).

An important part of the medical evaluation of an individual with autism spectrum disorders is measuring growth parameters: height, weight, and head circumference. A calculated BMI should be included at each health visit since obesity is a serious co-occurring health problem in people with ASD. Head circumference is often larger than average in early childhood in children with ASD. Medical problems that occur with greater frequency in people with ASD than the general population should be screened for in the medical evaluation and then routinely in health maintenance visits. While physical symptoms may be related to an etiologic cause of ASD, they may be related to core symptoms such as anxiety or repetitive behaviors. Anxiety appears to be related to both intestinal and sleep issues (Ferguson et al. 2017; Mazurek and Petroski 2015). All of these disorders may reflect differences in autonomic tone. Individuals with ASD should be monitored for the following associated medical problems:

- Sleep disorders like insomnia and night waking
- Gastrointestinal problems like constipation and selective eating
- Seizures
- Attention deficit hyperactivity disorder
- Anxiety disorders
- Wandering or elopement (the major cause of death in children with ASD is accidents)

The next level of testing depends on the combined information from the history and physical exam. Routine EEG and neuroimaging are not recommended by the American Academy of Pediatrics at this time. MRI is indicated with recent or atypical regression, an abnormal neurologic

exam, or a suggestive history for neurologic disease. EEG is indicated with recent or atypical regression or a history suggestive of seizures.

The current newborn screening in the USA will pick up many of the inborn errors of metabolism such as PKU, galactosemia, and congenital hypothyroidism. If the newborn screening was not completed or is not available, then metabolic testing with quantitative amino acids should be considered in a child whose history and physical exam suggest possible inborn errors. Maternal screening for rubella identifies pregnancies at risk for congenital rubella syndrome.

Comparative genomic hybridization microarray is considered the first-line genetic evaluation in the workup of ASD without a suspected specific etiology by the American College of Genetics. Studies report that from 10% to 17% of children with an ASD will have an abnormality on this testing (Shen et al. 2010). However, most of these abnormalities are considered benign. Children with intellectual disability, female gender, or dysmorphic feature may be more likely to have a genetic etiology identified from these evaluations (Roesser 2011). While comparative genomic hybridization (CGH) microarray can pick up a large number of duplications or deletions, there are some translocations that can only be seen on karyotype. Karyotype examination is often obtained when there is a family history of greater than two miscarriages or a specific diagnosis such as Down syndrome is suspected.

A newer technology, whole exome sequencing, evaluates the entire genetic code but focuses on areas with more functionally important genes (called the exome). The whole exome sequencing leads to confirmation of a syndromic diagnosis for 12–15% of children with ASD (Tammimies et al. 2015). Overall 30% of children with ASD are found to have genetic abnormalities on WES.

History and examination may guide the clinician to order testing for specific disorders associated with ASD. Genetic testing for Rett syndrome should be considered in girls diagnosed with ASD. They may demonstrate microcephaly or deceleration of head growth in early childhood. Other clinical markers of Rett syndrome include stereotypical hand movements and psychomotor

regression. Patients with webbing of toes, mildly dysmorphic features, or failure to thrive could have Smith-Lemli-Opitz syndrome. In this case, 7-dehydrocholesterol level should be sent. A lipid panel may also pick up the extremely low cholesterol level. Children with ASD and seizures should be considered for a possible diagnosis of Angelman syndrome. It is associated with a chromosome 15 abnormality in the same region as Prader-Willi syndrome. Boys with intellectual disability/learning disability should be considered for the DNA testing for fragile X syndrome especially if there is a family history on the maternal side of learning challenges. About 20–30% of children with fragile X will also have ASD. However the yield of fragile X testing in children with ASD is quite low at 0.05% (Roesser 2011; Chen 2011; Weinstein et al. 2017).

Children with macrocephaly may be at increased risk of PTEN (phosphatase and tensin homolog) gene mutations. PTEN mutations alter tumor suppression and are associated with hamartomatous syndromes such as Bannayan-Riley-Ruvalcaba syndrome and Cowden syndrome. Family members are at risk for tumors in the thyroid, breast, and uterus. Any child with macrocephaly and family history of any of these cancers should have genetic evaluation for PTEN mutations.

Referral to a geneticist may be indicated for assessment of genetic etiologies of ASD for genetic workup, evaluation for suspected metabolic disease, diagnosis of dysmorphic syndromes, and genetic counseling. Children with regression, movement disorders, microcephaly, neurocutaneous lesions, midline facial defects, abnormalities in neurologic examination, or a history of seizures may require referral to a neurologist. MRI may be necessary. A screening MRI is not necessary for macrocephaly alone or single café au lait spot. EEG may be needed if there is suspicion of seizures. Seizures are seen in 25% of children with autism.

Lead testing is not part of the routine etiologic workup for autism but could be considered for children with pica or for those at environmental risk if not previously obtained in the course of well-child care. Children with pica are at

continued risk of lead poisoning at a much older ages. Children with limited diets may benefit from nutritional evaluation to ensure adequate growth and development. Low iron stores might be associated with sleep problems related to restless legs syndrome. Iron stores may be low before anemia occurs.

Future Directions

Over time, genetic diagnostics have become more accurate. Initially testing could only identify large abnormalities using karyotype analysis. Now, smaller abnormalities can be detected. The technology is emerging, so the clinical significance of some of the findings is not clear. The use of large datasets will permit investigation of the relationship of specific genetic abnormalities, neurophysiologic profiles on EEG, and MRI findings with both etiology and treatment response (Payakachat et al. 2016). As the cost of genetic testing decreases and the implications of the results are linked with actionable steps in care, more individuals with ASD will be tested. New uses for MRI, functional imaging, and brain spectroscopy will be evaluated, and as the findings are linked to clinical decision-making, outcomes will change the recommendations for use.

Medical Home and ASD

Lisa Honigfeld and Judith Meyers
Child Health and Development Institute of
Connecticut, Farmington, CT, USA

Definition

An effective approach for delivering comprehensive pediatric primary care medical services to all children, including those with ASD.

Historical Background

Children with autism spectrum disorder (ASD) and their families receive many services delivered in their homes, schools, early care and education programs, and community agencies, but the primary health-care site plays a unique and significant role in the care for children with, and at risk for, ASD. Although all children may not receive home visiting services, or may not attend early care and education programs, more than 90 percent of young children, across all racial, ethnic, and socioeconomic categories, have a visit with a health provider each year (Department of Health and Human Services 2014). The American Academy of Pediatrics (AAP) guidelines for pediatric primary care, which are accepted by state Medicaid programs and commercial insurance plans, call for 13 well-child visits before school entry (American Academy of Pediatrics 2015), at which child health providers are to perform the following: immunizations, sensory and metabolic screenings, developmental screening, complete physical exams, and anticipatory guidance to support parents in raising their children. These visits provide child health providers with frequent opportunities to identify children who may have, or may be at risk for, ASD, connect them to diagnostic and intervention services, and monitor their health and development over time.

An effective approach for delivering pediatric primary care medical services to all children, including those with ASD, is the medical home

model. A pediatric medical home provides access outside of traditional office hours, continuity of care with a team of providers who work in partnership with families, linkage to medical and non-medical services outside of the practice, care that is coordinated across all services that children use, and services that meet the needs of all patients in a context that is respectful of their cultural and religious beliefs (Holt et al. 2010). Within the medical home model, several professionals participate in the care of children, including pediatricians, nurse practitioners, physician assistants, family physicians, and a variety of office staff members that include nurses, medical assistants, care coordinators, and administrative staff. A hallmark of the medical home model is that all staff members work together as a team with families to support the needs of the children served in the practice.

The AAP developed the medical home model to guide child health providers in the care of children with complex medical needs (American Academy of Pediatrics 1992), and the concept has since been expanded to recognize that all children can benefit from having a medical home (American Academy of Pediatrics 2004). The AAP specifically called out the role of medical home in the care for children with ASD in 2013 (American Academy of Pediatrics Autism Expert Panel 2013) with publication of a resource guide for child health providers. The guide includes information on early identification, screening tools, coding to ensure reimbursement, and informational handouts for families.

The medical home has also become the pervasive model of care for adults and is a popular component of health-care reform initiatives in several states (Van Vleet and Paradise 2014) that are working to transform their health-care delivery systems to contain costs, improve population outcomes, and enhance the patient experience. There are four national medical home accreditation programs, any one of which, when successfully completed, allows primary care practitioners to participate in enhanced payment programs offered through insurance plans (American Academy of Family Physicians 2015).

The widescale adoption of the medical home model is based on research showing that care from a medical home is of higher quality and costs less than care delivered in nonmedical home sites (Nielsen et al. 2016). For children with special needs, the medical home model has been shown to improve timeliness of care, health outcomes, family centeredness, and family functioning (Homer et al. 2008).

Current Knowledge

Parents of children with ASD are less likely to report that their child has a medical home than parents of children in general or of children with other types of special needs (Brachlow et al. 2007), despite national trends toward medical adoption, evidence that the model meets the needs of children with special needs, and incentives for child health providers to transform their practices to be medical homes. As a result, families with children with ASD have a harder time gaining access to specialty services (Cheak-Zamora and Farmer 2015) and are more likely than families of children with other neurological disorders to make their own connections to neurology services (Ming et al. 2011). Families of children with ASD who report having a medical home also report fewer unmet needs (Farmer et al. 2014) than children whose parents report that they do not have a medical home.

Lower levels of parent satisfaction with primary care as well as advocacy and education received are also reported by families of children with ASD compared to other children with special needs (Hyman and Johnson 2012; Carbone et al. 2010a). Pediatricians report that they are not adequately trained, lack the necessary time, and are challenged in meeting the needs of children with ASD and their families (Carbone et al. 2010b; Golnik et al. 2009).

In addition to providing accessible, coordinated, and family-centered care, the medical home entails specific responsibilities that ensure early detection of ASD among all their patients, connection of children for whom there are

concerns to diagnostic and intervention services, and ongoing monitoring of health and development.

Early identification of children with ASD is facilitated by developmental surveillance and screening for all children (American Academy of Pediatrics 2006). Developmental surveillance includes the following four major elements that support early detection of children with, or at risk for, developmental delays: soliciting parental concerns, maintaining a longitudinal record of development, observing the child, and obtaining input from individuals other than parents who care for the child (e.g., early care and education providers). Through developmental surveillance, child health providers can probe for clinical cues related to attention, social skills, and communication and facilitate early identification of children who may have ASD (Carbone et al. 2010b). Developmental screening relies on the use of a formal tool. The AAP recommends that child health providers screen for developmental delay at the 9-, 18-, and 30-month well-child visits (American Academy of Pediatrics 2006). The AAP also recommends that child health providers use a formal tool to screen specifically for ASD at the 18- and 24-month visits. The most commonly used screening tool for ASD in primary care is the Modified Checklist for Autism in Toddlers, Revised with Follow-Up (M-CHAT-R/F) (Robins et al. 2009). The tool, scoring instructions, and follow-up questions when parents report concerns on specific items can be obtained at no cost and in more than 30 languages, including several Spanish dialects. The M-CHAT-R/F includes 20 yes/no questions that parents can answer in less than 5 min; scoring by practice staff can be completed in 2 min. In many states, Medicaid and commercial insurers pay for screening on the same day as a well-child visit.

The M-CHAT- R/F is validated for use with children up to 3 years of age. Sometimes parents and child health providers have concerns about older children's social and communication skills and want to screen for ASD. The Childhood Autism Spectrum Test (CAST), previously called the Childhood Asperger Syndrome Test (Williams

et al. 2008), has been validated for use in pediatric primary care for children ages 4–11. It contains 37 items to be completed by parents and is available free of charge and in more than 15 languages.

When surveillance or screening shows concerns that suggest ASD, child health providers rarely perform next level diagnostic assessment but connect children and families to such services. Options for assessment are largely determined by resources available in the local area. Developmental pediatricians, behavioral health professionals, and neurologists may complete ASD and general developmental evaluations to verify a diagnosis. All states have early intervention (EI) programs under Part C of the Individuals with Disabilities Education Act. EI programs are required by the federal law to complete evaluations of children ages 0–3 with suspected developmental delay, including ASD, within 45 days of referral to the program. For children ages 3–5, Part B of the Individuals with Disabilities Education Act similarly requires timely evaluation upon referral. Part B and Part C programs also provide intervention services.

Although the therapeutic interventions for ASD will take place out of the medical home, there are several medical conditions that are associated with ASD and can be managed by pediatric primary care providers. These include epilepsy, gastrointestinal problems, and insomnia (Carbone et al. 2010b). Other conditions, such as motor impairments, sensory processing, and mental health disorders, which are also associated with ASD, may be identified in the medical home and require that the primary care provider connect the child to specialty services (Carbone et al. 2010b).

To meet the medical and nonmedical needs of children with ASD, the medical home actively connects families to services. Other providers in the community expect the pediatric primary care medical home to stay involved by taking on responsibility for acute health care, continued well-child visits, and physical and developmental monitoring. Because there is no cure for ASD, child health providers, who often provide care to children from birth to 21 years, can expect to be involved with a changing team of service

providers in the community as the child with ASD ages (Swiezy et al. 2008). These relationships span from early intervention and childcare providers for younger children to school personnel and employment services for older children. The medical home provider is often the single constant provider for families and children across the first 21 years of life and maintains a relationship with the family and comprehensive history that other service providers do not have. The role of the medical home in coordinating care over time is essential for ensuring best outcomes for children and optimal benefit from other services.

Family support is a critical component of care at the center of the medical home model that is often cited as lacking for children with ASD (Brachlow et al. 2007). In the same way that the medical home connects children and their families to subspecialty and intervention services, it also provides opportunities for families to connect with other families of children with ASD and with community family support opportunities. Many organizations exist for families of children with ASD, and the medical home maintains a list of those that are active in their specific community and contact information for them to give to parents. ASD parent support organizations, such as Autism Speaks, often have state and community level chapters, which offer a variety of services for families, including support groups, play groups, financial advising services, and recreational programs for children with ASD as well as general educational information. There is also a plethora of websites for families that provide information about ASD. Table 1 provides a list of some of the most popular sites. The medical home can have resources, such as this list, for families. There are

also several Facebook and other social media sites that promote a community among children with ASD and their families.

In addition to providing family support resources to families of children with ASD, the medical home also tailors its services to meet the special needs of these children. By the very nature of their condition, children with ASD may require special accommodations in the medical home, including longer visit times, shorter wait times, and accommodations for the performance of the physical exam (Volkmar et al. 2014). Many of the procedures that are expected when children visit the doctor are challenging for children with ASD, including undressing, answering questions, allowing physical contact, and cooperating for immunizations and lab testing. Linking children with ASD to dental and subspecialty services also requires special consideration, and the medical home can maintain a list of referral sources in the community that are known to care for children with special needs.

Beyond medical subspecialty and community services, pediatric medical home providers are responsible for connecting children with ASD when they turn 21 to adult health-care providers (Carbone et al. 2010b). This can present challenges for families and children as well as for the provider (Cheak-Zamora et al. 2013). A family is often reluctant to leave the health-care provider who has cared for their child since birth, and providers struggle with identifying adult medical providers who can care for the young adult with special needs and saying goodbye to longtime patients and their families. The AAP, American Academy of Family Physicians, and American College of Physicians have jointly endorsed a set of guidelines and activities for transitioning patients from pediatric to adult care (American Academy of Pediatrics 2015). The six core elements of transition, which the guidelines recommend should begin at age 12, include developing a practice transition policy for all children, monitoring and tracking transition activities for each patient, assessing transition readiness as part of well-child visits, collaborating with parents to develop a transition plan, preparing and implementing transfer of care with all necessary

information, and following up with families to ensure that transition was successful. The AAP provides several resources to help the pediatric medical home implement each of these elements.

Cultural competency is another important component of the medical home that pertains to children with ASD. Children who live in families who are of lower socioeconomic status, or are members of racial and ethnic minority groups, experience later identification of their ASD (Ennis-Cole et al. 2013). This could result from their parents having different expectations for child development and responding differently to screening questionnaires or developmental surveillance questions that are largely validated in middle-class populations. Utilization of intervention services for nonwhite and low-income children with ASD is also lower than for other children with ASD, suggesting that families from diverse backgrounds may be more reliant on family- and faith-based organizations than professionals to meet their children's needs (Ennis-Cole et al. 2013).

All national organizations that certify practices as medical homes (American Academy of Family Physicians 2015), thereby enabling them to obtain enhanced payment from insurers, require that practitioners participate in ongoing quality improvement activities. Care related to ASD is an excellent area for practice-based quality improvement efforts. Practices can track and improve their implementation of universal ASD screening in well-child care visits. They can also set up practice systems to ensure that children for whom screening shows concerns receive assessments and are linked to intervention services if needed. The AAP's transition tool kit (American Academy of Pediatrics 2015) includes a self-assessment tool that practitioners can use to obtain a baseline measure and then periodically reuse to assess progress in implementing a transition program.

Future Directions

With increasingly high rates of diagnosis of ASD in young children, the medical home model is

undergoing several refinements to ensure better care for this population. Autism-specific medical home models that include parents within the practice to provide peer support and guide service enhancements have shown improved patient outcomes and parental satisfaction and fewer unmet needs (Golnik et al. 2012). Another innovative model of implementing medical home for children with ASD is the health home, which embeds primary care medical services within a behavioral health setting specifically tailored to meet the needs of children with ASD or intellectual disabilities (Fueyo et al. 2015).

At the same time, as primary care medical homes are transforming their services to address ASD, other community providers are also striving to meet the needs of this growing population of children. The Hospital for Special Care in New Britain, Connecticut, was the first ASD specialty service to earn recognition from the National Committee for Quality Assurance. Coordination of care with the pediatric medical home was one component of the recognition process.

There are several challenges to improving the ability of pediatric primary care sites to care for children with ASD within the medical home model. These include the following: lack of training about ASD, reimbursement for time spent in treating and managing children with ASD, and lack of care coordination (Golnik et al. 2009). Training tailored to improve screening of all children is effective in supporting early detection of children with ASD at the population level (Honigfeld et al. 2012), and pediatricians are also eager to receive more training on the ongoing care for children with ASD (Golnik et al. 2009). Ideally such training would begin in medical school and be reinforced with clinical experience in pediatric residency programs, available for the duration of professional careers through continuing medical education and required for pediatric maintenance of certification. Multidisciplinary training opportunities that include health, education, behavioral health, and other service providers would enhance the common understanding of optimal services for children with ASD among the professionals who serve them.

Payment models beyond traditional fee for service, which are increasingly popular in public and private insurance plans, can also facilitate improved medical home care for children with ASD. Bundled payments that provide reimbursement for all of the care for chronic conditions would allow child health providers to spend adequate time addressing the specific challenges in examining children with ASD as well as family support needs. Insurance plans that pay a per member/per month or enhanced capitation payment can support the provision of the extensive care coordination and team participation that medical home providers need to optimally support children with ASD and their families.

In sum, the medical home model is ideal for the care of children with ASD. It can ensure early identification, linkage to diagnostic and intervention services, and ongoing health maintenance to support children's participation in therapeutic services. Enhanced training, payment for time and care coordination, and opportunities to support families can all contribute to increasing the contribution of the pediatric primary care medical home to the health and well-being of children with ASD.

Synonyms

Medulla

Definition

The *medulla oblongata* is the lowest of the three structures of the brain stem (the pons and the mid-brain are the other two), and as such, it participates in the brain stem's important role in serving as the modulator and integrator of any information exchange between the brain and the proprioceptive and exteroceptive systems of the human body. In the light of the fact that ASD is becoming recognized increasingly as a problem of the nervous system integrity involving many functions of the brain, one might predict that the brain stem, in particular medulla oblongata, would have a significant share in the neuropathology of ASD. In fact, earlier postmortem and MRI structural imaging studies on the brain stem found all three structures significantly smaller in individuals with autism (Gaffney et al. 1988; Hashimoto et al. 1993). These studies, however, suffered from the presence of confounding variables and were contradicted by concurrent and later studies, even though more recent volumetric studies of both white and gray matter continue to implicate the brain stem (Goldberg et al. 1999; Rodier 2002).

Neurochemical abnormalities in individuals with ASD have served as another link between medulla oblongata and autism. Serotonin is a neurotransmitter that is synthesized from tryptophan by neurons in the raphe nuclei of the brain stem reticular formation, which extends along all three structures of the brain stem. Autistic individuals have been found to have elevated whole-blood serotonin 5-HT levels and decreased tryptophan

Memantine

Lawrence David Scahill

Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA

Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA

Department of Pediatrics, Emory University, Atlanta, GA, USA

Definition

Memantine: Memantine is a selective blocker of a specific glutamate receptor in the brain. It is approved for the treatment of dementia. It is also used in combination with the cholinesterase inhibitors such as donepezil. Memantine is presumed to have beneficial effects on Alzheimer's dementia because of its blockade of this specific glutamate receptor. It has not been well studied in children or adults with autism.

Memory

Diane M. Lickenbrock

Human Development and Family Studies, The Pennsylvania State University, University Park, PA, USA

Synonyms

[Recollection](#); [Remembrance](#)

Definition

The multifaceted process of encoding, storage, and retrieving knowledge of things that we have experienced, imagined, and learned. Memory is often measured using tasks associated with recall, retrieval, or recognition. There are a wide range of memory abilities in individuals with autism spectrum disorder (ASD), with some showing significant impairments across multiple types of memory, and others showing “savant” skills. Most commonly, individuals with ASD have a profile of strengths and weaknesses that vary across specific subtypes of memory.

Memory Assessment

Jill Boucher

Developmental Psychology, Autism Research Group, City University, London, UK

Definition

The assessment of memory in ASD is carried out by researchers attempting to delineate the pattern of strengths and weaknesses in memory and learning in ASD generally and to understand the psychological, neurobiological, and etiological correlates of the atypical memory profiles delineated. Memory assessment may also be carried out by practitioners to delineate and understand atypical patterns of learning and memory in individuals with ASD with the aim of developing effective intervention strategies. Very little assessment of the neurobiological and etiological correlates of atypical memory and learning in ASD has been carried out, and what follows relates exclusively to the psychological assessment of memory.

Current Knowledge

Memory is involved in the acquisition, storage, retrieval, and everyday use of associations, habits, skills, perceptual images, words, facts, and personal experiences. It is therefore a critical component of all kinds of learning. People with ASD across the spectrum show certain atypical patterns of memory and learning, including some outstanding strengths as well as certain limitations. In lower functioning individuals with ASD, moderate or severe memory limitations contribute to clinically significant learning disabilities. At the same time, memory strengths in both lower and higher functioning individuals may be utilized in compensatory learning. It is therefore practically as well as theoretically important to characterize the pattern of memory strengths and weaknesses in people with ASD and to understand how and why uneven memory profiles occur, both generally and individually. This in turn requires that

appropriate investigative procedures are developed and used by researchers and that appropriate assessment tools are available to practitioners. A representative selection of experimental research procedures and clinical assessment tools is outlined below.

Experimental Assessment Procedures

The Assessment of Implicit, or Non-declarative, Learning

Many associations, habits, skills, and perceptual images are acquired “implicitly,” that is to say, without conscious awareness or control of what is being learned, although there may be an intention to learn. Moreover, what has been learned implicitly is not generally available to report – hence the term “non-declarative.” For example, babies work hard at learning to walk, oblivious of the increasingly well-entrenched changes in brain activity and muscle coordination that are occurring every time they struggle to their feet and stagger a step or two. Similarly, they unconsciously learn the sound system and grammatical rules of their native language without awareness of the rules and regularities they are acquiring. Because implicit learning takes many forms, it can be experimentally assessed in many ways. A few examples, all of which have been used in investigative studies of people with ASD, are given below:

- **Conditioning.** When used with vulnerable people, a typical conditioning test might consist of shining a dim light into an individual’s eye just before delivering a small puff of air onto the eyeball (as in a standard test used by opticians) which produces a reflexive blink, and measuring how many repetitions of this procedure are needed before the dim light elicits a reflexive blink in the absence of a puff of air.
- **Category Formation.** Basic-level categories relating to common objects, actions, or qualities are largely acquired implicitly from the first weeks of life onward. There are various theoretical models of how this is achieved. One well-authenticated model involves the (unconscious) acquisition of a prototype (e.g.,

the most typical form of a “dog” or a “tree”). A commonly used category formation task involves showing the examinee pictures of an imaginary creature (e.g., a “moodle”) defined by a particular set of probabilistic features (e.g., a longish and somewhat crooked nose, a shortish tail) and contrasting moodles with “non-moodles” (which in some ways resemble moodles, but which lack their prototypical features) by sorting into two piles. Examinees are then asked to try to sort a different set of moodles from the non-moodles with correction from the tester. A critical measure of category formation is whether or not representations of a prototypical moodle are correctly sorted.

- **Sequence Learning** (as, e.g., in acquiring motor skills, habitual routines, or other forms of “procedural” learning). A serial response task is commonly used to assess implicit sequence learning. In this task, a stimulus (e.g., an asterisk) appears in one of several locations on a computer screen in a repeating sequence, and participants respond to each appearance by pressing a corresponding key. Learning is demonstrated by a decrease in response time on trials when the locations follow the sequence and by an increase in response time on trials when locations do not follow the sequence.

The Assessment of Explicit, or Declarative, Memory and Learning

Words and their meanings, factual knowledge, and the content of personal experiences are at least potentially available to conscious awareness during learning and potentially available to subsequent report, hence the term “declarative.” The content of declarative memory may broadly be described as “things that we know that we know,” even if we need some prompting to recover the memory.

Whereas experimental tests of implicit learning in people with ASD are currently mainly directed toward answering the question “*Can* people with ASD do this?”, the peaks and troughs of explicit memory in people with ASD are already quite well established (Boucher et al. [in press](#)). In brief, the most able individuals with ASD have

good vocabularies (even though words may not always be used in entirely typical ways); they have excellent ability to acquire factual knowledge, especially relating to topics of special interest; but they have some difficulties in recalling personal experiences, especially the more subjective elements, such as how they themselves were feeling at the time. Less able individuals with ASD may have across the board difficulties with declarative memory. Because profiles of declarative memory abilities across the spectrum are relatively well established, experimental assessments of explicit learning are mainly directed toward answering questions concerning *why* the patterns of memory peaks and troughs occur and differ across the spectrum.

Declarative memory tests may be designed to investigate critical differences in the *kinds of things* examinees can or cannot easily remember. Critical differences that have been investigated in people with ASD include:

- The complexity of the material to be remembered (e.g., comparing the ability to recall lists of unrelated words, as opposed to related words, sentences, or stories; and pictures of single objects, as opposed to scenes)
- The social connotations of the material (e.g., comparing the ability to recognize pictures of faces as opposed to buildings)
- The extent to which the examinees themselves played a role in the action or event to be remembered (e.g., comparing memory for actions they themselves have carried out as opposed to those the tester carried out)
- The modality of the material to be remembered (e.g., comparing memory for spoken as opposed to written words)

Other tests are designed to investigate differences in the *learning and recalling conditions* that may contribute to memory peaks as opposed to memory troughs. For example:

- “Learning over trials” as opposed to “single trial learning.”
- “Intentional” as opposed to “incidental” learning, that is, tests in which the examinee is

instructed to try to remember the pictures they will be shown or the gist of the story they will hear as compared with tests in which they are simply shown some pictures or read a story and then unexpectedly tested for memory of what they have seen or heard.

- Computer-based as opposed to person-led learning.
- Recognition tests (which of these pictures did you see just now?) as opposed to free recall tests (what objects did you see in the pictures you saw just now?) and “free recall” as compared to “cued recall” tests (one of the pictures was of a kind of fruit/began with the sound “b”).
- Immediate as opposed to delayed memory tests.

Yet another group of experimental memory tests focuses on the *processes* that may underlie memory peaks as opposed to memory troughs in ASD. For example:

- Tests of encoding biases, such as tendencies to encode (register into memory) details of a scene rather than the scene as a whole; or the sound rather than the meaning of heard words
- Tests of retrieval processes (i.e., the processes by which what has been unconsciously learned or consciously memorized becomes accessible for use) and especially difficulties that people with ASD may have in effortful and strategic forms of memory search where few or no cues or prompts are available as opposed to associatively triggered memories or recall in response to informative cues or leading questions

The Assessment of Working Memory

“Working memory” involves the ability to maintain information in short-term memory while simultaneously operating on it in some way. Maintaining information in short-term memory is not by itself a major problem for people with ASD, as is evident from their good rote memory ability. However, the simultaneous maintenance and manipulation of information involve executive control and may be problematic. Experimental assessment of working memory in people with ASD is at the stage of delineating the kinds of

working memory tasks on which people with ASD reliably succeed as compared with those they find significantly difficult.

Some experimental assessments of working memory that have been used with people with ASD are described below:

- **Backward Digit Span.** In this task, the examinee must register and maintain in short-term memory a serially presented list of, for example, seven digits, and subsequently report the sequence in reverse order.
- **“N-back Tasks.”** In this kind of task, the examinee might be asked to name individual letters successively presented on a screen and to press a response key if the letter on the screen is the same as the last-but-one letter presented or the same as the last-but-two letter presented.
- **Self-ordered Pointing Tasks.** In this type of task, the examinee might be shown a set of line drawings of, for example, nine everyday objects located on a 3×3 grid. The set is reproduced nine times with no object appearing in the same location twice. The examinee is shown each reproduction in turn and instructed to point to a different item each time, requiring them to hold in mind a cumulative list of items already responded to.
- **Prospective Memory Tasks.** “Prospective memory” involves “remembering to remember” to do something, for example, remembering to take swimming things to school on a Wednesday, to post a birthday card to grandma tomorrow, and to take the saucepan off the hob at a certain time. Experimental tests of prospective memory generally involve giving an instruction such as “remember to press the red button whenever you see an animal on the screen/once a minute” and then giving the examinee some other task to be getting on with, such as sorting pictures on the screen by their color. The measure of prospective memory ability is the number of times the original instruction is acted on, either in response to the “event cue” (an animal occurring on the screen) or in response to the “time” cue (an internal estimate of 1 min).

Clinical Assessments

Most clinical assessments of memory have been developed for use with adults with medical conditions known to be associated with memory impairments or anomalies, such as head injury, stroke, Alzheimer’s disease, or posttraumatic stress disorder. Some of the best-known of these clinical assessments are designed to test a broad range of memory abilities. Others have been designed to assess in greater detail some specific form of memory. Versions of some assessment procedures developed for adults have subsequently been developed for use with children. Other procedures have been developed specifically for use with children and are not suitable for use with adults. A representative selection of clinical assessment procedures, all of which have been used for the assessment of memory in people with ASD, is listed below:

- *The Wechsler Memory Scale, 3rd edition* (Wechsler 1997). This widely used test consists of subtests assessing immediate auditory and visual-spatial memory and subtests assessing story recall, verbal paired-associate learning, face recognition, and recall of the content of pictures of family scenes, this latter group of subtests being assessed in both immediate and delayed recall conditions.
- *The Rivermead Behavioural Memory Test, 3rd edition* (Wilson et al. 2008). This test is designed to assess memory using materials and situations resembling everyday situations. So, for example, prospective memory is assessed, as is memory for a route, and learning to associate a name with a face. There is a children’s version of this test: *Rivermead Behavioural Memory Test for Children* (Wilson et al. 1991).
- *The Doors and People Test of Visual and Verbal Recognition and Recall* (Baddeley et al. 1994). This test, as its name indicates, is designed to assess person-related as compared to object-related memory, visual as opposed to verbal memory, and recognition as opposed to recall. It can be used with children as well as adults.

- *The California Verbal Learning Test-II* (Delis et al. 2000a). This test assesses memory for word lists in a variety of conditions, including comparisons of single trial versus multiple trial learning, immediate versus delayed recall, free recall versus recognition versus cued recall, and “old list” versus “new list” learning. There is a children’s version of this test: *The California Verbal Learning Test for Children-II* (Delis et al. 2000b).
- *The Autobiographical Memory Interview* (Kopelman et al. 1990). This test uses a structured interview format to probe the ability to recall facts and specific incidents from the individual’s past life, from childhood to recent time.
- *The Benton Face Recognition Test* (Benton et al. 1994). In this test, each test item consists of a black and white photograph of a face set above a choice of six other black and white photographs of faces in a variety of orientations, and examinees must indicate whether one or more of these are of the person in the target picture.
- *The Rey-Osterrieth Complex Figure Copying and Memory Test* (Osterrieth 1944). As the name of this test suggests, examinees are first asked to copy a complex abstract figure. This is then removed, and the examinee is immediately asked to draw the figure again, this time from memory. Following a delay, they are again asked to draw the figure from memory.

Tests developed specifically for use with children include:

- *The Wide Range Assessment of Memory and Learning* (Sheslow and Adams 1990). The content of this test broadly corresponds to the content of the adult-targeted Wechsler Memory Scale (see above).
- *The Children’s Memory Scale* (Cohen 1997). The content of this test also corresponds broadly with that of the Wechsler Memory Scale. More specifically, it is described as assessing verbal and visual memory; short delay and long delay memory; recall, recognition, and working memory; and the role of attentional factors in memory.

- *The Children’s Nonword Repetition Test* (Gathercole and Baddeley 1996). This test of immediate short-term memory assesses the ability to repeat accurately a series of made-up words of increasing length.

The above list represents only a small selection of clinical assessment procedures, and many more are available and have potential value for better understanding the nature and causes of uneven memory abilities in ASD. A comprehensive list of assessment procedures can be found in Lezak et al. (2004).

Memory Development

Sebastian Gaigg and Dermot Bowler
Autism Research Group, City University London,
London, UK

Definition

The concept of *Memory Development* may appear to require few introductions, but closer inspection reveals certain complexities that are important to note. For one, the notion of development must not be misunderstood as referring exclusively to the changes in behavior and cognition that accompany infancy and early childhood. Although this early stage of development is of key interest, important changes also take place later in life, and since adults come to be the way they are through their developmental history, they must not be overlooked as a rich source of information about developmental processes. Just as the

archeologist is able to infer what events took place in a distant past from the study of ancient treasures, so the developmental psychologist can make certain inferences about the principles of development by taking a close look at adult behavior. What also renders the concept of memory development complicated is the fact that “memory” is far from the transparent phenomenon that our common usage of the term may have us believe. Whether we forget the name of a person we have just been introduced to, the capital of a country we once visited, the location of our car in a car park, or a certain sequence of key strokes on the piano, we are always quick to blame our *memory* for our failures. Yet, decades of research have shown that such instances of forgetting are not the result of the failures of a single memory system or process but of the imperfections of a number of such systems and processes that each contributes in specific ways to our ability to learn from the past. It is beyond the scope of this entry to provide a summary of the various approaches that have been taken to carving the nature of memory at its joints (for overviews relevant to the study of autism, see Gardiner 2008 and Mottron et al. 2008), but two distinctions require a brief comment. The first is the division between *procedural* and *declarative* memory. Procedural memory describes memory for sequences of motor behaviors that can be learned and expressed without the necessary involvement of conscious awareness. Declarative memory, by contrast, describes memory for information that is learned and retrieved under the influence of conscious awareness. This entry will only concern issues relating to declarative memory development since the vast majority of research in autism has addressed this domain. The second distinction is based on the observation by Tulving (1985) that not all of our declarative memories are associated with the same kind of conscious experience. The memory of the name of our childhood primary school, for instance, is qualitatively different from that of our first day there. The former is associated with a *noetic* sense of awareness (knowing) that is relatively void of a feeling of personal belonging. It characterizes retrieval from our *semantic memory system* that

constitutes a store of impersonal facts and knowledge about the world. *Autonoetic* awareness (remembering), by contrast, accompanies retrieval from our *episodic memory system*, which encompasses all those memories that revolve around our “self” in the past. These distinctions are critical when considering how memory develops since the lack of language during the earliest stages of development makes it impossible for infants to “declare” what they remember and how they remember it. As a result, the study of memory development in very young children is complicated, and when language development follows an atypical trajectory, such as in the case of autism, matters become even more intricate. It is thus perhaps not surprising that the study of memory development in autism has adopted the archeological route of focusing on adults as a source of information. The patterning of memory strengths and weaknesses in older groups has provided important clues about what role disturbances in memory development may play in the origin and/or maintenance of the clinically defining manifestations of autism, and together with advances in the methods for studying how memory matures during the first few years of life, these clues are beginning to open promising new research avenues for the near future.

Historical Background

Memory research in autism has a long history that begins with the seminal work of Beate Hermelin and Neil O'Connor in the 1960s (Hermelin and O'Connor 1970). At that time, cognitive approaches and associated computer analogies of the mind/brain relation dominated the field of psychology, and autism was finally beginning to be accepted as a neurodevelopmental disorder rather than the consequence of pathological parenting. In the context of these developments, Hermelin and O'Connor set about to determine how the autistic mind *processed* and *stored* information, and they soon made a discovery that remains valid up to the present day. In a series of experiments, they demonstrated that children with autism did not benefit from “meaning” when

trying to remember sets of stimuli. For instance, whereas typically developed children would remember grammatically correct sentences far better than random sequences of words, children with autism would remember both sets of stimuli equally well. Similarly, children with autism did not demonstrate a mnemonic advantage for meaningfully related as compared to unrelated words or pictures, while children without autism reliably did. Together these findings led Hermelin and O'Connor (1970) to conclude that autism was characterized by an impairment in processing information meaningfully and numerous subsequent studies have lent support to this suggestion. Another early discovery was the observation that tests of free recall pose disproportionate difficulties for individuals with autism. Free recall relies almost exclusively on the operations of the episodic memory system and requires the retrieval of previously learned information with only minimal support (e.g., “Tell me all the words you can remember”). Boucher and Warrington (1976) showed that children with autism were significantly impaired in recalling namable pictures, written words, and spoken words despite performing similarly to comparison children when retrieval cues were provided at test (e.g., “Can you remember something you sit on” for the item “stool”). Importantly, this pattern highlighted a parallel with patients who suffered damage to an area of the brain known as the hippocampus, leading Boucher and colleagues to conclude that this medial temporal lobe (MTL) structure was likely to play a critical role in the neurodevelopmental origins of autism (see Mayes and Boucher 2008 for a recent review of the relevant evidence).

As ahead of their time as these early pioneers were, their insights and discoveries were soon to fall by the wayside in favor of other conceptual developments in the field. The discovery that children with autism lacked a “theory of mind” (Baron-Cohen et al. 1985) began to dominate the search for the developmental origins of the disorder during the 1980s and the formulation of the weak central coherence (WCC) theory around the same time soon appeared to provide an elegant explanation for the findings by Hermelin and

O'Connor (1970) in terms of a detail-focused rather than a holistic and meaning-focused processing style in autism (e.g., Shah and Frith 1993). In addition, it was thought that the kind of memory difficulties experienced by individuals with autism could not possibly contribute causally to the development of the disorder since the memory processes relevant to these difficulties (i.e., primarily episodic processes) were widely thought not to mature until the age of 3–4 years in the course of typical development. In other words, there was a widespread conviction that memory difficulties emerged after the clinically defining symptoms of the disorder. For the next 20 years, therefore, the dominant topic of discussion was the nature of the relationship between the detail-focused processing style of individuals with autism and their difficulty in understanding the minds of others. Research on memory merely continued at the fringes of scientific awareness. Today, however, developments in both the autism memory literature and the mainstream memory development literature are beginning to draw attention to the possibility that atypical learning and memory processes may play a much more important role in the development of autism than originally thought.

Current Knowledge

In order to understand why interest in the learning and memory difficulties of individuals with autism is growing, it is necessary to provide an overview of the developments in two distinct literatures – that concerning the patterning of memory strengths and weaknesses in autism and that concerning how memory typically develops during the first years of life.

Memory Strengths and Weaknesses in Autism

As already alluded to, our current knowledge about memory function in autism stems primarily from studies of children, adolescents, and adults who have sufficient language and general intellectual abilities to cope with the demands of declarative memory tasks. Work with these

relatively high-functioning individuals generally confirms the original conclusions by Hermelin and O'Connor (1970) and Boucher and colleagues (e.g., Boucher and Warrington 1976) that individuals with autism experience difficulties in drawing on meaning to facilitate memory and that their performance on free recall measures is disproportionately attenuated compared to supported test procedures such as cued recall and recognition. Close scrutiny of these phenomena in recent years, however, has led to a more refined understanding of why a difficulty in drawing on meaning should coincide with disproportionate difficulties in free recall, and three sets of observations have proven particularly informative in this context. First, it is now widely accepted that autism is characterized by impairments in episodic memory that go beyond a disproportionate difficulty with free recall procedures. For instance, when individuals with autism are asked to describe the quality of their memories on tests of recognition memory (e.g., “Have you seen X before?”), they are less likely than comparison participants to recollect specific details about the study episode (e.g., Bowler et al. 2007). Individuals with autism also struggle to recall contextual details such as when, where, and how they learned something when they are directly tested for such details (e.g., Bowler et al. 2004; Poirier et al. 2011), and they often adopt a third-person rather than a first-person perspective when recalling autobiographical events (Lind and Bowler 2010). The second influential discovery is that, contrary to the original conclusions by Hermelin and O'Connor (1970), individuals with autism appear to draw on “meaning” to facilitate memory under several circumstances. For instance, conceptual relations between words (e.g., crop-grain) have been shown to promote memory in autism as much as in comparison groups when recognition procedures (“Did you see the word apple earlier?”) rather than free recall procedures (“What words did you see earlier?”) are used (e.g., Bowler et al. 2008) or when attention is drawn to such relations during study (Gaigg et al. 2008; Mottron et al. 2001). In addition, individuals with autism are as likely as comparison participants to experience false memories of words that

are meaningfully related to a set of studied words (e.g., night, pillow, tired, bed, dream. . . for a false memory of *sleep*) (Bowler et al. 2000; Hillier et al. 2007), which suggests not only that the concept of “meaning” is too broad to capture what individuals with autism do not process effectively in the service of memory but also that memory difficulties in this disorder are unlikely to be a reflection of a local processing style as proposed by the WCC theory. The third development that has contributed to our understanding of the patterning of memory strengths and weaknesses in autism is the complex information processing framework developed by Minshew and colleagues (see Williams et al. 2008), which notes that memory difficulties in this disorder become more pronounced as tasks become informationally more complex. For instance, Minshew and Goldstein (2001) found that individuals with autism demonstrate a progressively more pronounced memory difficulty for materials that increase in semantic and syntactic complexity from sequences of letters to sequences of words and sentences. Although these observations are consistent with Hermelin and O'Connor’s original observations, Minshew and Goldstein (2001) also found that when asked to learn the path through a maze, individuals with autism compared to those without performed progressively worse as the number of choice points in the maze increased, and this finding is less amenable to an explanation in terms of “meaning.” Taken together, therefore, these findings favor the view that it is “complexity” rather than “meaning” that lies at the root of the memory difficulties in autism, which is also consistent with neuropsychological evidence implicating the frontal lobes in autism (see Williams et al. 2008 for a review). But what is the metric for complexity? How can it be measured and defined, and how does the concept of complexity account for the episodic memory difficulties outlined above? The answer to these questions lies in the mainstream memory literature where a distinction between *item-specific* and *relational* processes (e.g., Hunt and Einstein 1981) will lead back to a developmental consideration of the role memory abnormalities may play in the ontogenesis of autism.

The Mainstream Literature

Around the time of the first systematic investigations of memory in autism, Hunt and Einstein (1981) proposed that the efficacy of memory is principally dependent on the processing of two types of information – item-specific information and relational information. *Item-specific* information is information specific to the individual elements of a to-be-remembered set of materials such as the fact that a banana is yellow, that it is sweet, that it is soft textured, and that it belongs to the category of fruit. *Relational* information, by contrast, is information that defines the relations between elements such as the fact that a banana is similar to a prune. Critically, relational information presupposes item-specific information. One can only relate banana and prune if relevant item-specific knowledge about the banana and prune is available. In other words, the processing of relational information is computationally more complex because it requires (1) the retrieval of item-specific information about elements of experience and (2) the formulation (not necessarily explicitly) of a relation between elements on the basis of such item-specific knowledge.

Bowler and Gaigg (2008) have argued that a definition of Minshew’s “complexity” in terms of item-specific (simple) and relational (complex) information provides a powerful tool for explaining the patterning of memory strengths and weaknesses in autism (see also Bowler et al. 2011 for an up-to-date review). For one, the distinction between relational and item-specific processing is widely thought to parallel that between episodic and semantic memory. More importantly, the distinction also helps to resolve the complex pattern in which “meaning” modulates memory in autism. The observations from memory illusion paradigms are particularly well suited to illustrate this point. In such paradigms, participants study lists of words of meaningful associates of one nonpresented item (e.g., night, pillow, tired, bed, dream. . . for *sleep*). Individuals with autism tend to recall fewer words from to-be-remembered lists in such tasks, but they nevertheless also fall prey to erroneously recalling the nonstudied target words (Bowler et al. 2000). This apparent paradox is explained by the fact that veridical recall of list

items depends on the effective processing of the relations between the items on the list, which, as noted earlier, also involves the bringing to mind of item-specific information about each individual word. False recall of the critical item, on the other hand, is largely the result of it being brought to mind by each of the studied words on the list. The critical word, in other words, constitutes part of the item-specific knowledge one has about the list items. Although this interpretation may seem contrived, it receives support from direct tests of the hypothesis that relational but not item-specific processing is compromised in autism (e.g., Gaigg et al. 2008) and from the neuroscientific literature (see Eichenbaum 2004; Mayes and Boucher 2008; Williams et al. 2008 for relevant reviews).

As noted earlier, until the 1980s, it was widely assumed that children were unable to form long-lasting declarative memories until the age of around 3–4 years. This view was mainly based on the fact that adults can rarely remember events from the first years of life, which seemed to suggest that no such event memories (i.e., episodic memories) are formed during early childhood. Just as archeologists can make mistakes in inferring the origin of certain artifacts, however, so developmental theorists can draw erroneous conclusions about developmental processes on the basis of adult behavior, and the domain of memory development provides a case in point. As it turns out, infants as young as 9 months can remember a surprising amount when tested with appropriate procedures (see Bauer 2006), and the most relevant to the study of autism is the observation that typical infants between 9 and 18 months rapidly acquire abilities that are indicative of relational memory processes. For instance, between 9 and 18 months, infants become increasingly proficient at deferred imitation tasks. In such tasks, an experimenter typically demonstrates a random sequence of actions such as banging a metal ring on a stick, then spinning the ring, and finally balancing it on a block. Following a delay of hours or even weeks, the infant who observed this sequence is presented with the same objects and encouraged to use them. Strikingly, by age 9 months, infants not only imitate the actions but they imitate them significantly above chance in the order in which they were

demonstrated. Since the ordering of events in memory is widely regarded as a product of episodic memory and relational processes (in this case temporal relations are processed), this provides strong support for the idea that relational memory processes begin to develop toward the latter stages of the first year of life (Bauer 2006). Additional evidence for this suggestion stems from intricately designed eye-tracking studies that assess novelty preferences in infants through visual paired comparison tasks. In such tasks, infants are first presented with a series of pictures, and after a short delay, they view the same pictures again alongside new and unfamiliar ones. In standard versions of this task, infants as young as 6 months demonstrate novelty preferences by visually exploring the novel picture for longer which indicates that they recognize the familiar one. Importantly, 6–9-month-olds do not demonstrate novelty preferences when tested in a different room to that in which the pictures were first seen. Such context dependence is thought to reflect a relative immaturity in relational processing since memory representations of the pictures are inflexibly bound to the memory representations of the context in which they were presented. The great advantage of mature relational processes is that they endow us with the ability to flexibly combine and recombine elements of past experiences, and this flexibility begins to emerge by about 12 months when infants begin to show novelty preference irrespective of context changes (see Jones and Herbert 2006; Jones et al. 2011 for further details). Importantly, the first reliable behavioral markers of autism are not evident until around 18–24 months, considerably later than the period during which relational processing capacities emerge in typical development.

Future Directions

The above overview is incomplete and oversimplified but nevertheless demonstrates that it is conceivable that memory atypicalities in autism emerge before the clinically defining features of the condition. In itself, this does not necessarily indicate that memory abnormalities are causally responsible for the clinical features of autism, but

it is a hypothesis that is in desperate need of empirical evaluation. The growing mainstream literature on relational memory development provides ample methodologies that can readily be adapted for this purpose, but in addition, there are other research directions that a relational processing hypothesis of autism invites. These directions are informed by a growing literature, which suggests that relational memory processes are not merely important for what we may narrowly consider to constitute “memory.” For instance, it is now well established that episodic memory and associated relational processes are not only important for dwelling on the past but also for imagining, predicting, and planning for the future (Schacter et al. 2008). Relational processes are also well established to be critical for a form of reasoning known as *transitive inference*, which allows us to make inferences such as “Paul is taller than Bob” given that “Paul is taller than Mark” and “Mark is taller than Bob,” and to infer relations among objects or subjects that share a common relation with a third object/subject (e.g., Susan knows Mary because Susan is Bill’s wife and Mary is Bill’s aunt) (Eichenbaum 2004). Relational processes are also critical for our ability to navigate three-dimensional environments (Eichenbaum 2004), and recent evidence also suggests that relational processes are important for certain forms of category learning (Zeithamova et al. 2008), analogical reasoning (Hummel and Holyoak 2003), symbolic and conceptual thinking (Kumaran et al. 2009), and, most importantly, understanding false belief (Bowler et al. 2005 and see Bowler et al. 2011). In short, there is absolutely no doubt that a disturbance in the typical development of relational processing capacities could have widespread repercussions on other areas of cognition, some of which have already been implicated in autism, others await closer scrutiny.

First “period”

Definition

Menarche is the medical term for the onset of menstruation, which is the periodic shedding of the uterine lining in females of reproductive age. Menarche is a hallmark of puberty and is often colloquially referred to as the first “period.” It typically follows thelarche (breast development) by approximately 2 years. In general, females must have at least 17% body fat in order for menarche to occur. The average age of menarche in the United States is between 12.1 and 12.6 years, with some variations across ethnic groups. African American females have a lower average age of menarche. The average age of menarche has been declining in developed countries over the last 150 years, likely as a result of improved adolescent nutrition. Low body weight and poor nutrition can delay menarche. Anovulatory cycles and irregular menses often occur in the first few months following menarche (Joffe 2006).

Girls on the autism spectrum may reach menarche later than the general population, but the

reasons for this delay are unclear. Proposed mechanisms include the role of elevated body mass index as well as increased exposure to androgen hormones during the prenatal period, though this hypothesis is controversial (Whitehouse et al. 2010). Children with autism often experience worsening symptoms during puberty (Knickmeyer et al. 2006). Autistic girls may be at increased risk for mood and behavioral disturbances around menstrual periods. More research is needed regarding the use of oral contraceptive pills (OCPs) for treatment of mood disturbances related to menses in this population (Burke et al. 2010). Medications that are commonly used to treat aggression and mood disturbances in children with autism can cause menstrual irregularities. For example, atypical antipsychotic medications can be associated with weight gain and elevated prolactin levels which in turn can impact the menstrual cycle.

The association between maternal early life factors and autism spectrum disorders is a subject of ongoing research. Maternal factors such as early menarche (age of menarche 10 years or less) and late adolescent obesity (body mass index greater than 30) are possibly linked to autism spectrum disorders (Lyall et al. 2010).

Meningitis

Martine Solages

Child Study Center, Yale University, New Haven, CT, USA

Synonyms

Meningococcal disease: a specific form of meningitis that is caused by the bacteria *Neisseria meningitidis*

Definition

The brain and the spinal cord are surrounded by three membranes that are collectively termed meninges. *Meningitis* is inflammation of the meninges that is typically caused by infectious agents such as viruses, bacteria, fungi, and parasites. There are also noninfectious causes of meningitis, including certain drugs, malignancies, and autoimmune diseases. Classic clinical signs of meningitis are fever, headache, neck stiffness, light sensitivity (photophobia), and alterations in consciousness. These symptoms may be absent or difficult to appreciate in infants and very young children. Meningitis can also be associated with nonspecific systemic symptoms such as irritability or loss of appetite. Seizures and focal neurologic deficits can occur as well. The gold standard for diagnosis of meningitis is the lumbar puncture procedure, during which a sample of the cerebrospinal fluid (the fluid encircling the brain and spinal cord) is removed for analysis.

Viral meningitis is relatively more common than other forms and usually resolves without specific medication treatment. Bacterial

meningitis is less common than viral meningitis, but is associated with higher morbidity and mortality and requires antibiotic therapy. The most common bacterial causes of meningitis are *Escherichia coli* and group B streptococcus in neonates, *Streptococcus pneumoniae* and *Haemophilus influenzae* type b in older children, and *Neisseria meningitidis* in adolescents. The incidence of bacterial meningitis caused by *Streptococcus pneumoniae* and *Haemophilus influenzae* has decreased since the introduction of a vaccination program against these bacteria. It is advised that children receive a series of vaccinations against *Streptococcus pneumoniae* and *Haemophilus influenzae* between the ages of 2 months and 15 months. Routine vaccination against *Neisseria meningitidis* is recommended at the 11–12-year-old well-child visit. Older children who have not yet received this vaccine should be vaccinated at the earliest opportunity. Unvaccinated or incompletely vaccinated children are at higher risk of acquiring bacterial meningitis as are children who are immunocompromised. Intellectual disability, seizure disorders, hearing loss, developmental delays, and behavioral disturbances can all be sequelae of bacterial meningitis.

Introduction

Autism spectrum disorder (ASD) is a heterogeneous disorder recognized by deficits in social communication and interaction, in addition to restricted and repetitive behaviors and interests (American Psychiatric Association 2013). ASD is also heterogeneous in terms of which symptom

emerges when and when the complete symptom pattern required for a diagnoses become evident. This leads to substantial difficulties in clinical detection and treatment planning. Research show that there is great variability in terms of etiology, behaviors, core symptoms, cognitive skills, adaptive skills, language and communication, the onset of diagnosis and core symptom patterns (Zwaigenbaum et al. 2015). For some, ASD symptoms required for a diagnosis may first become evident when social demands exceeds the capabilities of the individual (Ozonoff et al. 2015). Additionally, symptoms of ASD may manifest differently depending on other factors, such as the child's cognitive abilities and verbal and nonverbal levels of functioning (Chawarska et al. 2014).

The term "mental health" might be understood widely as the emotional, psychological, and social well-being of humans, as well as having few or no mental health problems. Furthermore, our mental health affects how we regulate ourselves, and how we cope with negative experiences, mending social relationships and make choices in challenging settings (WHO 2018). However, the term is frequently used intertwined with psychiatric conditions, which if present, naturally affects the emotional, psychological, and social well-being of that person. Furthermore, mental health in a wider perspective is also associated with the term Quality of Life (QoL), where aspects of both influence the well-being in all human beings.

Most research conducted on mental health related to autism is focused on issues of well-being, stress, and QoL in parents of individuals with ASD (Factor et al. 2018; Halstead et al. 2018; Leadbitter et al. 2018; Lecavalier et al. 2018; Nordahl-Hansen et al. 2018; Salomone et al. 2018; Schiltz et al. 2018), and it is well established that parents of children with ASD are at a higher risk of experiencing mental health problems often associated with increased levels of stress, anxiety, and depression (Lecavalier et al. 2018; Nordahl-Hansen et al. 2018; Øien and Eisemann 2016). Currently, it is far less investigations of mental health in individuals with ASD and has for many years been an under-researched topic (Burgess and Gutstein 2007).

In terms of quality of life, research have revealed that individuals with ASD reports lower levels of QoL than those without an ASD diagnosis (Ayres et al. 2017). Aside from studies on the QoL of individuals with ASD, very few studies to date have directly assessed the mental health of individuals with ASD. Increased focus on research related to improving mental health, well-being, and QoL in those with ASD have the potential of revealing factors of importance in terms of preventive interventions for developing psychiatric conditions. As of now, we know far less of how persons with ASD experiences factors in their own life, and how these influences their trajectories to better or worse mental health and QoL.

Current Knowledge

Currently, there is an understanding that having ASD in itself implies significant challenges for those affected and their families, and with a particular strain when ASD is accompanied by other comorbid or coexisting psychiatric conditions such as anxiety, depression, or with having acute and increasing levels of stress (Benson and Karlof 2009; Lai and Oei 2014; Nordahl-Hansen et al. 2018). It is, however, important to highlight that the term mental health comprises far more than the presence or absence of a psychiatric condition (WHO 2018). Mental health is also about the emotional and social well-being, happiness, as well as having a sense of safe and meaningful life.

Also, it is important to distinguish the terms comorbid and coexisting as representing two different terms. *Comorbidity* refers usually to a state when two diagnoses are present and the conditions are related to each other, while *coexisting* refers to when two diagnoses are present without necessarily being related, i.e., being diagnosed with ASD and diabetes are coexisting conditions, while ASD and intellectual disability (ID) are comorbid conditions (Kaplan et al. 2016).

In terms of prevalence of psychiatric conditions found in individuals with ASD, Simonoff et al. (2008) reported that 70% of children with an ASD diagnosis had one comorbid diagnosis,

while 41% had two or more (Simonoff et al. 2008). This indicates that psychiatric comorbidities are very common in ASD and often presents in higher proportions that would be expected compared to what is known from prevalence in the general populations. Studies have revealed that the most common psychiatric diagnoses are social anxiety disorder, attention deficit hyperactivity disorder (ADHD), and oppositional defiant disorder (ODD) (Mattila et al. 2010; Simonoff et al. 2008). The increased prevalence of comorbid psychiatric conditions or problems in ASD might indicate that a substantial portion of individuals with ASD have poorer mental health and quality of life due to the consequences of the psychiatric condition/problem. However, we do not know how the interplay between having comorbid conditions and having a feeling of quality of life, well-being, and happiness are. It is a knowledge gap in research on understanding what constitutes factors of importance in a preventive perspective as for the development of poor mental health.

It is important to acknowledge that the heterogeneity in symptom patterns in ASD can manifest in different ways, and symptoms can appear similar to phenomena found in other psychiatric conditions (Kaplan et al. 2016). However, it might be that psychotic-like symptoms in individuals with ASD are better explained as a part of their underlying ASD diagnosis and related to specific cognitive challenges and as such will have different implications for our understanding, treatment, prognosis, and access to services (van Schalkwyk et al. 2015). This highlights the need to be cautious in adding diagnosis in individuals with ASD, as they might be associated with different factors than found in non-ASD individuals and as such require different strategies for treatment. However, it is equally important to provide evidence-based treatment for persons with ASD in the case of having other coexisting clinical problems.

A plausible model of what contributes to good/poor mental health in ASD is bidirectionality, where symptoms related to the core of ASD directly affects socio-emotional well-being negatively, increasing the likelihood for developing

psychological problems or conditions such as anxiety and depression, which further spiraling the socio-emotional impairment downwards.

As ASD is recognized by its core deficits in social communication and interaction (American Psychiatric Association 2014), affecting the opportunities they have to establish and maintain social relationships with others, often leading to loneliness and even social anxiety (Bauminger and Kasari 2000; White and Roberson-Nay 2009) (Cacioppo et al. 2006; Leary 1990). Little research has been devoted to understanding the positive mental health development in individuals with ASD, and very few measures have been developed with the purpose of providing how they perceive their own emotional, psychological, and social well-being.

Future Directions

As very few to this date have conducted research on mental health-related phenomena such as the emotional, psychological, and social well-being of individuals with ASD (mental health), future studies should aim at investigating measures that can shed light on mental health in those with an ASD diagnosis. There is, an increasing interest in conduction research on how individuals with ASD perceive their quality of life, and specific measures for this purpose are starting to emerge (Ayres et al. 2017; Burgess and Gutstein 2007; McConachie et al. 2017). There are great difficulties in ascertaining information directly from different subpopulations within the Autism spectrum in regards to ability of an interest in reflecting on quality of life (QoL), emotional, psychological, and social well-being. Many persons within the spectrum have severe intellectual disability and might have little functional language. It is still of paramount importance to develop relevant, valid, and reliable observational measures to use as proxy measures used by parents or other who know the child well. Expected outcomes would be to understand the interplay between everyday conditions that influences the trajectories of mental health issues (positive or negative). In addition, exploring if children with different symptom

patterns constitute different risk markers for a positive or negative development. There has been made some advances in terms of what parents highlights as the most important measures of outcomes to target in interventions (McConachie et al. 2018). Their highest ranked outcomes impacted directly on everyday life and functioning (anxiety, distress, hypersensitivity, sleep problems, happiness, relationships with brothers and sisters, and parent stress) (McConachie et al. 2018). Furthermore, it is important to investigate in further depth how a diagnosis of ASD might not only make them more at risk for developing psychiatric conditions affecting mental health but also how core features of ASD mediate mental health outcomes. More importantly, investigating what constitutes good mental health in individuals with ASD is of great importance to develop new measures.

Longitudinal studies following children and adolescents could potentially provide information on which factors that predict later psychiatric conditions in individuals with ASD and other neurodevelopmental disorders. Such studies could also identify sex-specific information, as well as preventive factors for negative mental health development.

Cognitive delay; Developmental disability (Ontario); Intellectual disability; Learning disability (UK)

Definition

The condition associated with subaverage intellectual functioning has undergone many changes in name and definition since it was first recognized (circa 1493; Scheerenberger 1983). In fact, the term “mental retardation” is no longer current; “intellectual disability” is the currently accepted term. Although a complete history of terminology and classification of intellectual disability is outside the scope of this entry, the highlights of the past quarter century follow. The term *mental retardation* replaced the term *mental deficiency* in 1987, and the condition underwent several minor definition changes during the following 25 years. Perhaps the most significant change to the definition occurred in 1992 when the concept of support was introduced as a fundamental aspect of the classification system. The current diagnostic criteria for intellectual disability are based on three criteria: (1) *significant limitations in intellectual functioning*; (2) *significant limitations in adaptive behavior expressed in conceptual, social, and practical adaptive skills*; and (3) *age of onset before the age of 18* (Schalock et al. 2010).

Throughout history, people with intellectual disabilities have been devalued and stigmatized. As such, the terms associated with this condition quickly acquire the stigma and are used pejoratively in common vernacular. Earlier terms such as feeble-minded, idiot, moron, imbecile, and mentally deficient each acquired social stigma and became offensive and hurtful to people with intellectual disability and their families. In recent years, the term mental retardation has acquired a derogatory connotation. For this reason, self-advocates, parents, and administrators sought an acceptable substitute. Rosa’s Law, signed into effect on October 5, 2010 by President Obama, changed the official federal terminology from mental retardation to intellectual disability. This law was preceded by the American Association on Intellectual and Developmental Disabilities who made the name change in 2007 and the state of Maryland who made the change in 2009. The change from mental retardation to intellectual disability was a change in name only; there was no

change in the diagnostic criteria, which allowed individuals receiving services under the term mental retardation to continue receiving the same services without interruption.

- 1975–1979 Psychologist, Division for Disorders of Development and Learning, University of North Carolina at Chapel Hill
- 1974–1975 Postdoctoral Fellow, Clinical Child Psychology, Division for Disorders of Development and Learning, University of North Carolina at Chapel Hill

Major Honors and Awards

- 1982 President, Society of Pediatric Psychology (Section 5 of the American Psychological Association Division of Clinical Psychology)
- 1982 Certificate of Appreciation for Contributions to Developmentally Handicapped Citizens of North Carolina (Awarded by Orange County, NC Association for Retarded Citizens)
- 1984 Fellow Status, American Psychological Association Divisions 37, 12
- 1989 Distinguished Professional Contribution Award, Society of Pediatric Psychology, American Psychological Association
- 1990 First recipient of Mesibov Award, given annually by Residential Services, Inc. for excellence in community-based residential service system for developmentally handicapped children and adults in Orange County, NC
- 1994 Opleidingscentrum (Belgium) International Award for contributions translating theory into effective practice in autism
- 1994 Mary G. Clarke Award from the North Carolina Psychological Association given annually to a psychologist in North Carolina for outstanding contributions spanning several years. Contributions must reflect qualities of dedication, competence, high ethical standards, advocacy for the field of psychology, and sensitivity
- 1995 MAPP (International organization to help More Able Autistic People) Award for invaluable service to the organization and to high-functioning people with autism
- 1997 Distinguished Professional Contributions Award for Public Service, American Psychological Association
- 2000 “Doctor Honoris Causa” (Honorary Degree) from the University of Mons-Hainaut

(Belgium) for contributions to improving the quality of life for people with autism throughout the world

- 2000 Emily and Frank Puzio Award from the Eden Institute's Princeton Lecture Series for leadership in improving the quality of life of individuals with autism
- 2006 UNC Chancellor's Award for Excellence for meritorious accomplishments clearly above and beyond what is expected in human relations
- 2006 NC State Employees Award for Excellence representing outstanding performance. This is the highest award an NC state employee can receive
- 2010 Danish National Autism Society Professional of the Year for doing the most to advance treatment and education of people with autism spectrum disorders
- 2010 American Association on Intellectual Developmental Disabilities Award for service to people with disabilities.
- 2010 Autism Society of America Founders Award for career substantive contributions to the field of autism spectrum disorders
- 2011 Honorary Degree from the University of Northampton (UK) for contributions to the education of children and adults on the autism spectrum

Landmark Clinical, Scientific, and Professional Contributions

Gary B. Mesibov has dedicated his career as a psychologist to autism. His contributions include a major assessment instrument; a book series; a comprehensive program of educational, vocational, residential, and family support services; and a unique training program for other professionals. His reputation among students, families, and professional colleagues is one of wisdom, generosity, compassion, and amazing productivity. He brings intellectual rigor to his professional activities and combines it with gentleness and respect for all clients and their families. His influence began in North Carolina and has spread throughout the world.

Short Biography

Gary B. Mesibov defended his doctoral dissertation in psychology at Brandeis University in the spring of 1974. Shortly thereafter, he arrived at the University of North Carolina at Chapel Hill as a post-doctoral fellow in the Division for Disorders of Development and Learning (DDDL). Gary's time at the DDDL marked the beginning of his professional identification with the field of developmental disabilities. Recognized as a gifted and prolific psychologist, after only 18 months, Gary was asked to accept a staff position at the DDDL with an appointment as an Assistant Professor of Psychology in the Department of Psychiatry. Gary's quiet passion for understanding and serving people with developmental disabilities soon led to professional involvement with newly developing service models in North Carolina, including group homes, sheltered workshops, limited guardianship, and social skills training, as well as service on a human rights committee at the regional residential facility for people with severe/profound intellectual disabilities. Gary conducted research, introduced students to the rewards and fascinations of developmental disabilities, and worked closely with clients and families. At the same time, he was teaching in the Department of Psychology, supervising interns and postdoctoral fellows in the Department of Psychiatry, and devoting considerable time and effort to the development of the Society of Pediatric Psychology (Section 5 of the American Psychological Association's Division 12).

Chapel Hill had long been a center of excellence in the field of developmental disabilities. In addition to the DDDL's broad-based training program in developmental disabilities, a small, psychoanalytically oriented program on autism had functioned for some years within the Department of Psychiatry. In 1966, this program was expanded and refocused by Eric Schopler and Robert Reichler on the assumptions that autism was a neurobiological disorder and that parents and professionals could work as cotherapists to help children with autism develop. In 1972, that program was renamed TEACCH (Treatment and Education of Autistic and Related Communication-Handicapped Children) and

funded by the North Carolina General Assembly as the nation's first statewide autism program.

Eric recruited Gary in 1979 to assume the new position of Coordinator of Adolescent and Adult Services at TEACCH. Four years later, Gary became Associate Director; 5 years later, codirector; and in 1992, with Eric Schopler's semiretirement, Director of Division TEACCH. Gary served in this position for 18 years until his retirement in 2010. This was a formative period for the organization as it grew to nine regional centers across the state of North Carolina, serving thousands of individuals on the autism spectrum. It was also a period of both broadening and deepening TEACCH's philosophical underpinnings and, as a result, its approach to intervention for individuals with autism. Eric had first understood the importance of using structure to help children with autism focus and learn; Gary elaborated on the principles of structured teaching and applied them to classroom, vocational, and residential settings. He also emphasized the importance of improving the quality of life for individuals on the autism spectrum, not merely addressing "deficits" or "behavior problems." In 2004, Gary coauthored *The TEACCH Approach to Autism Spectrum Disorders* as an introduction to the TEACCH philosophy, structured teaching, and its application across a wide range of contexts.

From 1983 until 1998, Gary and Eric coedited the "Current Issues in Autism" series for Plenum Press. These books were based on the yearly TEACCH conference held in Chapel Hill each May. The conference has drawn noted autism experts such as Margaret Bauman, Eric Courchesne, Geraldine Dawson, Christopher Gillberg, Temple Grandin, Cathy Lord, Sally Ozonoff, Michael Rutter, Oliver Saks, Wendy Stone, and Lorna Wing. Conference speakers uniformly, and quite independently, speak with affection and admiration for Gary's contributions. Throughout the years, he has demonstrated a remarkable capacity to maintain warm, personal relationships with professionals around the world.

Like most respected academics, Gary began to be asked to give talks or provide training outside his hometown. In the late 1970s, his talks were in rural North Carolina, with occasional well-timed presentations at the Atlantic coast in the summer.

By the 1980s, he was accepting invitations to Kentucky, Ohio, Georgia, Florida, and Oregon. During this time, he was also developing a unique, week-long, multimodal training program for teachers and other professionals working with students with autism. Gary and a training team would arrive at a location on Sunday, set up a model classroom with local students with autism on Monday morning, and take turns giving didactic lectures and operating the classroom. The trainees would observe trainers working with the students and then take over themselves, designing and presenting teaching activities that put into practice the principles they had been hearing in the lectures. After the local students went home for the day, there would be small-group and large-group debriefings of what trainees had tried, what had worked, and what had not worked. This model classroom has been presented every summer since 1985, training more than 2000 teachers of students with autism. Gary and his teams have also presented the classroom and other types of training in Australia, Belgium, China, Denmark, England, France, Germany, Hong Kong, India, Italy, Japan, Kuwait, Mexico, New Zealand, Northern Ireland, Norway, Pakistan, Qatar, Russia, Saudi Arabia, Singapore, Sweden, and Venezuela.

Gary was also involved in developing the Adolescent and Adult Psychoeducational Profile (AAPEP), an assessment instrument for adolescents and adults with autism. In 2007, he and his colleagues issued a major revision of the instrument, renamed the TEACCH Transition Assessment Profile (TTAP), in order to assess more accurately the skills needed for successful employment in community settings and to promote independent functioning in the home, workplace, and community. Gary's vision and leadership have been the impetus behind TEACCH's Supported Employment Program, which continues to be one of the most successful such programs in the nation for adults with autism.

Gary served for 10 years as editor of the *Journal of Autism and Developmental Disorders* and on the editorial boards of the *Journal of Pediatric Psychology*, *Journal of Clinical Child Psychology*, and *Journal of Cognitive Rehabilitation*, in addition to being a guest reviewer for almost a dozen other journals. Over his career, Gary has

earned a reputation as someone who can translate basic research into everyday practice. In recent years, he has helped the autism community think carefully about “evidence-based practice” and how this concept can be applied to specific autism interventions and to broad-based program models.

Gary’s many professional awards demonstrate his commitment to advancing the science and practice of psychology while maintaining a clear focus on improving quality of life for individuals with autism across the lifespan. For example, he received the 1997 American Psychological Association’s Distinguished Professional Contributions Award for Public Service. He has received honorary doctoral degrees from the University of Mons-Hainaut (Belgium, 2000) for “contributions to improving the quality of life for people with autism throughout the world” and from the University of Northampton (United Kingdom, 2011) “for his contribution to the education of children and adults on the autism spectrum.” In 2006, Gary received the University of North Carolina at Chapel Hill Chancellor’s Award for “meritorious accomplishments” on behalf of the university. In 2010, he was named “Professional of the Year” by the Danish Autism Society for “doing the most to advance treatment and education of people with autism spectrum disorders.” Also in 2010, Gary received the Autism Society of America Founders Award for “career substantive contributions to the field of autism spectrum disorders.” These are just the highlights from a career marked by recognition from parents and professionals alike.

Since stepping down as director of Division TEACCH, Gary has found a bit more time for his grandchildren, but he has not lost his passion for improving the quality of life for individuals with autism, particularly for adolescents and adults. He continues to inspire the TEACCH staff and the autism community at large to embrace “the culture of autism” as a metaphor for understanding the unique qualities of the children, adolescents, and adults they serve.

Definition

Mesoridazine is a prescription drug in the group of piperidine phenothiazines in the family of first-generation antipsychotics whose active ingredient

mesoridazine besylate has the chemical formula $C_{27}H_{32}N_2O_4S_3$. This drug was initially FDA-approved for medical use in the year 1970 and was produced by the company Novartis, but the production of this drug has been discontinued. This compound has relatively low potency compared to the other first-generation antipsychotics, and its mechanism of action is thought to involve anticholinergic binding. This drug is FDA-approved for the treatment of schizophrenia and can be used to treat aggressive symptoms. Observed side effects include drowsiness/sedation, Parkinsonism, akathisia, orthostatic hypotension, tachycardia, electrocardiogram (ECG) abnormalities, anticholinergic effects, sexual dysfunction, galactorrhea, and weight gain.

Metabolic Testing

Jessica L. Roesser

Department of Pediatrics (SMD), University of Rochester, School of Medicine and Dentistry, Rochester, NY, USA

Description

Definition

Metabolic testing is the laboratory evaluation looking for inborn errors of metabolism. Inborn errors of metabolism are genetic or inherited conditions that cause symptoms because of a lack of a necessary enzyme or biochemical process that results in the inability to convert substrates into the appropriate biologic product in the body. Some inborn errors of metabolism result in toxic accumulations of substances that cannot be metabolized, and others have symptoms that result from a deficit in production of necessary biochemical compounds.

Specific biochemical tests are used to examine the metabolism of compounds such as amino acids, carbohydrates, fatty aldehydes, organic acids, peroxisomes, lysosomes, and others.

Background

Inborn errors of metabolism are seen in the general population at a rate of 0.1–0.4%. It has been suggested that they may be identified in 3–5% of children on the autism spectrum. However, there are many types of inborn metabolic disorders, and each type is extremely rare. Categories of inborn errors of metabolism include metabolism of carbohydrates or sugars, problems with processing protein or amino acids, mitochondrial disorders, storage disorders, disorders of steroid metabolism, and many others.

Metabolic testing may be ordered to look for rare causes of developmental disability in the presence of a history of regression, a family history of early childhood deaths or regression, specific symptoms consistent with a metabolic disorder, or findings on physical or neurologic exam suggesting a metabolic disorder might be present. Metabolic testing is performed through newborn screening in every state in the United States. Different panels are included in newborn testing in each state. Some allow families to refuse. Newborn screening takes a few drops of blood dried on a filter paper that are then evaluated using very specific methodology. Most states include PKU, galactosemia, biotinidase deficiency, congenital adrenal hyperplasia, maple syrup urine disease, tyrosinemia, and other non-metabolic disorders like hypothyroidism, sickle cell syndrome, and cystic fibrosis.

The symptoms of inborn errors of metabolism might occur at birth, sometime in the first 3 years of life or later depending on the disorder and whether their might be some residual metabolic function. Some disorders like phenylketonuria occur when the placenta no longer compensates for the metabolic error. In other situations, decompensation occurs during a serious illness or major stressor. Others are progressive such as infantile ceroid lipofuscinosis, biotinidase deficiency, and Sanfilippo syndrome.

Abnormalities on newborn screening typically require additional testing to confirm that a problem exists. Specific tests are used for each of the identified metabolic disorders. A specialist such as a geneticist or child neurologist often must consult to help guide the evaluation.

The first inborn error of metabolism to benefit from widespread newborn screening was phenylketonuria or PKU. It is due to an absence of the enzyme that metabolizes the amino acid phenylalanine into tyrosine. Without this enzyme, a toxic metabolite builds up and results in neurologic impairment. This is the most common of the inborn errors of metabolism and is seen in 1 in 10,000 live births. The treatment for this is diet by limiting intake of Phe. Untreated children with PKU developed intellectual disability and often autism. The prevalence of autism in PKU has dropped from 20% to around 5% due to early

detection and treatment with diet. Even if PKU is treated with diet, there is a slightly higher chance of lifelong neuropsychiatric problems including ASD (Bilder et al. 2017). If PKU is identified early, the child will have fewer problems. Newborn screening in all US states and Canada detects PKU; however, children born in areas that do not have newborn screening might still be evaluated for this disorder (Baieli et al. 2003).

As in phenylketonuria, an increasing number of metabolic disorders have interventions that improve outcome. While the following are not associated with ASD, they are causes of developmental disability that have treatments that can change outcome if identified on newborn screening. Children with galactosemia, a disorder of sugar metabolism, if untreated will develop cataracts, kidney failure, liver failure, and brain damage. Galactosemia can be treated with dietary elimination of galactose. Children with biotinidase deficiency can have variable presentation but, if left untreated, can have developmental delays, vision or hearing loss, seizures, ataxia, hair loss, and/or candidiasis (a fungal infection). This is treated in some cases with oral biotin and avoiding raw eggs, which decrease absorption of biotin. Tyrosinemia is another disorder of protein metabolism that causes intellectual disability and kidney and liver damage. It is treated with low-protein diet and liver transplant if needed. The most severe form of the organic aciduria, maple syrup urine disease, causes vomiting, dehydration, hypotonia, seizure, brain injury, pancreatitis, coma, and ultimately death. Symptoms are prevented with dietary modification. Other inborn errors may be seen in children with nonspecific symptoms, and many are without specific treatments to date. The disorders included in newborn screening programs are ones that are not as rare and have interventions that prevent symptoms.

Mitochondrial disorders occur when there are mutations in the maternally derived mitochondrial genes. Mitochondria are small organelles that are involved in producing energy in each cell of the body. These organelles contain their own genetic code that is separate from the genetic code in the nucleus. The mitochondria are contained in the egg, but not in the sperm, so all mitochondria

and their DNA are inherited from the mother. However, the mother might have fewer and less intense symptoms, or possibly more symptoms, depending on the number of functional mitochondria that are inherited. These disorders are rare in the general population and no screening tests are accurate. It has been suggested that there is an increased rate of mitochondrial abnormalities among children with ASD. Metabolic findings on laboratory testing could be causative or may be secondary to other causes of the symptoms of ASD. Mitochondrial dysfunctions result in increased oxidative stress and changes in energy metabolism. Symptoms suggestive of mitochondrial disorders are excessive fatigue, severe hypotonia, cyclic vomiting, visual problems, hearing problems, poor growth, and/or seizures. Specialized testing including muscle biopsy may be necessary to identify mitochondrial disorders. Specialists in metabolic genetics or child neurology are consulted.

Treatment Goals

Metabolic testing includes an array of specific biochemical analyses ordered as part of a medical workup of an individual with a history and physical examination suggesting evaluation of a specific category of metabolic disorders.

The goal of the metabolic testing is to identify a specific inborn error of metabolism. Some of these inborn errors of metabolism have identified dietary or vitamin treatments that can help limit or improve the symptoms. Many inborn errors of metabolism do not have a known effective treatment. New therapies are under study for many disorders that range from dietary modification, pharmacologic replacement of enzyme, and gene therapy. Diagnosis of an inborn error of metabolism helps families understand the etiology of the developmental disability or other symptoms present in the child and allows for counseling regarding heritability. Specific treatment interventions may be recommended.

Metabolic testing is not routinely done to evaluate the nutritional status of children with limited diets.

Clinical Uses

The level of metabolic testing indicated varies from child to child and situation to situation.

All children should have some form of newborn screening to identify the most common and most treatable types of inborn errors of metabolism.

Children diagnosed with ASD should have a thorough history and physical exam done by a medical professional with experience in autism spectrum disorders. Additional testing for metabolic disorders is not required in every child with an autism spectrum disorder (Myers 2007; Campistol et al. 2016). Children with a history of unusual regression later than age 3 or regression with illness, weakness unexplained by other causes, organomegaly or other evidence of storage disorders, significant hearing impairment, eye findings consistent with a metabolic disorder, or other findings suggestive of a specific etiology should be considered for metabolic evaluation. Children with autism and history of severe seizures especially those resistant to treatment may also be considered for underlying metabolic etiologies. Unusual gastrointestinal disturbances, especially cyclic vomiting or frequent vomiting with mild illness, may indicate metabolic disorder. Children with prominent hypotonia, ataxia, movement disorders, or motor regression may also be considered for metabolic testing based on history and physical examination.

For many of these children, referral to a geneticist or metabolic expert is the most efficient way to focus the metabolic evaluation. For most patients, a tiered level of testing is done. The least invasive tests indicated by the symptoms that are most likely to give information are ordered first and then work up based on the history to more invasive testing like skin or muscle biopsy.

Metachromatic Leukodystrophy

Alexander Westphal¹ and Miranda Farmer²

¹Division of Law and Psychiatry, Yale Child Study Center, Yale School of Medicine, New Haven, CT, USA

²Yale Child Study Center, New Haven, CT, USA

Synonyms

MLD; Scholz's disease; Sulfatide lipidosis; Sulfatidosis

Short Description or Definition

Metachromatic leukodystrophy (MLD) is a rare genetic disorder that worsens over time. Symptoms are primarily neurological and related to white matter degeneration, although other organs can also be affected. Psychiatric symptoms often occur. In the early stages, MLD may be confused with autism.

Categorization

Metachromatic leukodystrophy (MLD) is a degenerative white matter disease, which is also classified as a lysosomal sphingolipid storage disease. Given the sudden neurological regression associated with MLD, early stages of this disease can sometimes be confused with autism spectrum disorders, including childhood disintegrative disorder and Rett disorder. As MLD progresses, the pronounced neurological symptoms distinguish it from autism spectrum disorders.

Epidemiology

MLD is classified as rare, with an estimated prevalence ranging from 1:40,000 to 1:100,000 among individuals of European descent. However, higher prevalence has been recorded in several small ethnic groups such as Navajo Indians in the United States and Habbanite Jews and Arabs in Israel.

MLD is caused by a deficiency of arylsulfatase A, a lysosomal enzyme that helps degrade cerebroside sulfate. As a result, sulfatide builds up intracellularly. This occurs primarily in Schwann cells and oligodendrocytes, causing demyelination and decreased white matter.

Over 100 mutations have been identified as a cause of MLD, making it genetically quite heterogeneous. Among Caucasian patients affected by MLD, 2 alleles are common, A and I. Together, these account for roughly 50% of cases. Furthermore, there is a well-documented genotype-phenotype correlation in MLD. Homozygosity for null alleles such as I, which do not yield any enzyme activity whatsoever, always produces the

most severe form of the disease, with late infantile onset and rapid progression. In contrast, homozygosity for alleles such as A that allow low levels of enzyme activity is typically associated with adult onset and gradual progression. Heterozygosity for both types of alleles typically produces an intermediate form of MLD, though there is significant overlap between juvenile- and adult-onset forms.

There are three onset patterns of MLD, described in more detail in the next two sections. Between 40% and 50% of cases are classified as “late infantile,” 30–40% as “juvenile,” and around 20% as “adult.”

Natural History, Prognostic Factors, Outcomes

There are three main forms of MLD, differentiated according to age at onset. Further differentiation can be made according to the pattern of progression and symptoms. Late infantile MLD arises in the first 2 or 3 years of life. Progression is typically rapid; patients succumb to the disease within 5–6 years. In this form, neurological symptoms are usually the first sign, though early stages of MLD can cause behavioral changes such as social regression and withdrawal. In adult-onset MLD, it is more common for psychological and behavioral symptoms to appear first, with neurological impairment appearing slightly later on. Early on, this form of MLD can be confused with schizophrenia, though the emergence of neurological symptoms clearly distinguishes the two. In contrast to late infantile MLD, progression in the adult form is much more gradual. This type of MLD typically emerges early in adulthood, though some cases have described onset as late as 50–60 years of age. Juvenile-onset MLD begins between the ages of 3 and 16, with widely variable progression. Symptoms can develop as rapidly as the late infantile form, yet some patients can survive into early adulthood.

Clinical Expression and Pathophysiology

The ultimate phenomenology of all forms of MLD is thought to result from demyelination of

neurons, triggered by an accumulation of sulfatide in oligodendrocytes, Schwann cells, and neurons. This accumulation is caused by a deficiency of the enzyme arylsulfatase-A, which is responsible for degrading sulfatide. Although the accumulation of sulfatide appears to trigger demyelination, the mechanism is not yet clear.

As mentioned above, MLD has several patterns of onset. Initial symptoms vary both across and within the subtypes of MLD. Here we focus on the early infantile- and juvenile-onset forms, which, when accompanied by a pronounced regression, may initially be difficult to distinguish from regressive ASDs, such as childhood disintegrative disorder and Rett disorder, but also may have subtle enough initial onset patterns to be mistaken for a previously “unrecognized” ASD. Dramatic regressions of the type seen in both childhood disintegrative disorder and Rett disorder are most commonly associated with the late infantile form of MLD. Generally this form of MLD is accompanied by neurological signs, including gait disturbances, and abnormal movement patterns. It can also be accompanied by a more general loss of developmental milestones, including speech, cognition, and self-help skills. Abnormal movement patterns may be interpreted as the hallmark repetitive behaviors of other ASDs. When coupled with developmental losses, these changes may be interpreted as an ASD. However, a careful neurological exam may reveal other changes, e.g., depressed deep tendon reflexes, positive Babinski sign, and muscular hypotonia, not consistent with ASD (although Rett disorder is also accompanied by neurological changes). Early infantile MLD progresses rapidly, however, to severe neurological signs, including spastic quadriplegia and severe dementia, and ultimately death. The juvenile onset of MLD can manifest more subtly in changes in school performance, psychiatric symptoms, etc. Sometimes the first neurological signs can be as subtle as clumsiness and poor coordination. Once again, when subtle, it is easy to imagine that this constellation of symptoms could be interpreted as a previously unidentified ASD. These symptoms may be static for an extended period, sometimes even years. However, a neurological exam may reveal the changes described above. Once the disease begins

to declare itself in clear neurological signs and symptoms, the progression generally becomes more rapid and similar to early infantile MLD.

Evaluation and Differential Diagnosis

The majority of signs and symptoms of MLD are neurological. Thus, a detailed neurological exam is an essential first step in evaluating suspected MLD, or for that matter, any deterioration of adaptive skills. Subtle neurological signs which point to the early stages of MLD may be picked up on exam, even if there are no obvious neurological deficits. The disease can sometimes first be manifested in behavioral changes. Therefore, it is important that any workup for a developmental derailment, as commonly seen in the ASDs, includes MLD on the differential. However, with the progress of MLD, dramatic neurological disturbances are inevitable and will be obvious both clinically and on exam. Neuroimaging, in particular MRI and MRS, may be a powerful tool in establishing a diagnosis. Areas of T2 hyperintensity (see fMRI section), initially in the periventricular areas but spreading from there, may be the first sign. Other findings are common. For a review of this topic, please see Kim et al. (1997) or Gieselmann and Krägeloh-Mann (2010). Laboratory testing is important. Both blood and urine will show evidence of MLD. The level of arylsulfatase enzyme activity can be tested in the blood leukocytes. Elevated urinary excretion of sulfatide over a 24-h period is also a sensitive marker. There are limitations to genetic testing for MLD due to the large number of mutations that can underlie the disease. Prenatal diagnosis of MLD can be done using cells from chorionic villi. The differential diagnosis for MLD includes a number of psychiatric disorders during the early stages, including attention disorders and psychotic disorders. Later, degenerative neurological disorders, including other leukodystrophies such as Krabbe disease, dominate the differential. Most relevant to this discussion, the combination of developmental derailment, including social changes and the loss of adaptive milestones, coupled with subtle neurological signs can suggest an ASD. Any evaluation of new ASD should

include MLD on the differential, with heightened suspicion in cases of regressive ASD.

Treatment

Therapeutic options for MLD are limited. In some cases, hematopoietic stem cell transplantation can be beneficial, but only under a limited set of conditions (see Gieselmann and Krägeloh-Mann 2010). A number of experimental therapies are being explored currently, including enzyme replacement therapy and gene therapy. However, at this point, there is no cure for MLD.

Metacognition in Autism

Kym Craig¹ and Catherine Grainger²

¹Heriot-Watt University, Edinburgh, Scotland, UK

²Psychology, University of Stirling, Stirling, Scotland, UK

Definition

“Metacognition” can be thought of as “thinking about thinking.” More specifically, metacognition is characterized as one’s awareness of and ability to regulate one’s own mental states (Flavell 1979).

John Flavell (1979), who originally termed the definition, established a taxonomy of metacognition, distinguishing between “metacognitive knowledge,” an individual’s beliefs and knowledge about cognitions (including declarative knowledge, procedural knowledge, and knowledge about strategy use), and “metacognitive skills,” an individual’s ability to assess and control their own cognitive processes. Since Flavell’s seminal work, researchers have reinterpreted and adjusted Flavell’s original definition. Currently, most researchers agree that metacognitive skills involve reflective processes that monitor and increase the efficiency of underlying cognitive processes in a number of ways. Take for example the various adaptive metacognitive processes involved in completing a study task. Metacognitive skills are required to form a representation of one’s existing learning and comprehension, evaluate the demands of the task and subsequently choose the appropriate strategy for task completion, monitor one’s progress towards the task goal (perhaps adjusting strategy use), and reflect on one’s decisions/performance during and after task completion (Flavell 1979; Lai 2011).

Unsurprisingly then, metacognitive processes are often considered essential for successful learning and a wide range of literature has explored the relation between metacognitive accuracy and learning success. In particular, accurate metacognition seems to be associated with good study skills. Additionally, training metacognitive skills appears to increase academic achievement (e.g., Flavell 1979; Perry et al. 2018; Van der Stel and Veenman 2014).

Moreover, metacognitive abilities are not just important for schooling/academic achievement. Knowing your own thoughts is crucial to accessing therapeutic treatments. A central pillar of common therapies, such as Cognitive-Behavioral Therapy (CBT) and Mindfulness-Based Therapy, is the ability to identify and reflect on one’s own cognitions. Indeed, recent research has suggested metacognitive accuracy may moderate the efficacy of CBT in children (Jones et al. 2019). Additionally, poor awareness of one’s own emotions appears to influence the outcome of psychodynamic therapy in adults (Ogrodniczuk

et al. 2011). As such, impairments in metacognitive skills likely make it difficult to implement psychological therapies successfully. However, this topic remains understudied, and more research is required to understand the relationship between metacognitive abilities and therapeutic efficacy.

Historical Background

The root of the word autism comes from the Greek word “*autos*,” which directly translates as “self.” Historically, autism has been linked to theories surrounding the self, with early theories conceptualizing autism as an extreme form of egocentrism (Bleuler 1950; Kanner 1943). Indeed, Leo Kanner originally “borrowed” the term autism from the work of Bleuler, who had coined it to describe an extreme self-focus and social withdrawal in his patients (with schizophrenia). In contrast, other theories have attributed various autistic behaviors to having an “absent self” (Frith 2003). While it is now well accepted that autistic individuals do not lack a sense of self, a growing body of research suggests that certain aspects of self-representation may pose challenging to autistic individuals.

Current Knowledge

While metacognitive research in the wider literature has been ongoing for 40 years, researchers have only recently begun to explore metacognitive skills in autism. To date, there are only 25 published studies that have investigated metacognition in autism, with somewhat equivocal results concerning autistic metacognitive abilities. While the majority of these studies suggest metacognitive impairments can be seen in autism (e.g., Grainger et al. 2014; Williams et al. 2018), other studies find metacognitive accuracy to be entirely typical (e.g., Grainger et al. 2016), or report mixed results (see Wojcik et al. 2013; Cooper et al. 2016). Such heterogeneous results make it difficult to make strong conclusions surrounding global metacognitive abilities in autism. Mixed

findings within the literature may be associated with methodological issues within the existing literature; firstly, not all existing studies of metacognitive accuracy in autism have matched their autistic group and comparison group for both age and cognitive ability. While matching for baseline variables is essential in all between-group studies of cognition in autism, this is particularly true for studies of metacognition, given the wider literature that suggests both age and cognitive ability strongly correlate with metacognitive accuracy.

Another possible explanation for mixed findings within autism research is that studies exploring metacognition in autism have employed a wide range of metacognitive tasks, as well as self-report measures, across different underlying domains (e.g., meta-memory, meta-perception). It is likely that self-report measures of metacognitive skills do not measure the same underlying processes as explicitly as those assessed using behavioral measures (Craig et al. *in press*). There is often little consistency between self-reported abilities and metacognitive performance on a task, in both nonautistic and autistic adults (see Grainger et al. 2016). Additionally, recent findings suggest that metacognitive skills in autism appear unimpaired, when assessed using implicit measures of metacognition (e.g., Carpenter et al. 2019; Nicholson et al. 2019). This may suggest a dichotomy between implicit and explicit metacognitive skills in autism, though it is important to note that the underlying processes driving performance on implicit tasks in autistic and nonautistic individuals may differ (see Nicholson et al. 2019 for a discussion of this in more detail).

There does appear to be some consistencies across research findings when patterns of metacognitive performance are broken down by specific task type. Generally, studies find that autistic participants are not as accurate as nonautistic participants when judging explicit confidence in their own performance (see Carpenter et al. 2019 for a review). In contrast, on tasks that ask participants to make judgments-of-learning (JOLs), concerning how well they think they have learnt information, we consistently find no evidence of metamemory impairments in autism (see Grainger et al. 2016; Wojcik et al. 2014). Another “classic”

measure of meta-memory (one's abilities to represent one's own memory states) asks participants to make feeling-of-knowing (FOK) judgments. During a typical feeling of knowing task, participants are tested to see if they can recall some recently learned information (e.g., a list of words). After recall ability is assessed, participants are then asked to assess the likelihood that they would know/recognize information (e.g., words) they currently cannot remember (e.g., assessing the likelihood of correctly recognizing words from a recently learned word list, which you currently cannot recall off the top of your head). Both published studies of FOK accuracy in autism report poorer accuracy on an FOK task compared to comparison participants (Grainger et al. 2014; Wojcik et al. 2013), though Wojcik et al. only found impairments when the FOK judgments assessed participants' episodic memory for unrelated word pairs and not when FOK judgments assessed semantic general knowledge of word-picture pairs. Differences in accuracy in autism across confidence judgments, FOK tasks, and JOL tasks are interesting from a theoretical point of view. Within the typically developing literature, researchers have questioned the idea that individuals (autistic or nonautistic) have stable metacognitive abilities that are employed across different tasks, arguing against a general metacognitive ability. These arguments are largely driven by findings that an individual's metacognitive accuracy does not always appear consistent across tasks, nor demonstrate strong test-retest reliability. Importantly, only domain-general accounts of metacognition predict consistent metacognitive accuracy across tasks/domains in autism.

Finally, to date few studies have considered the role co-occurring conditions may have on metacognitive skills in autism. Research suggests that mental health conditions, such as anxiety or depression, are particularly common in autism (see Simonoff et al. 2008). For example, while estimates suggest that ~10% of individuals in the general population demonstrate high levels of alexithymia (a subclinical condition characterized by difficulties identifying and describing emotions), studies suggest that 50% of autistic individuals may meet the criteria for alexithymia (Hill

et al. 2004). It is important to acknowledge high levels of co-occurring conditions in autism, given findings that metacognition is impacted by mental health conditions. Those with high levels of depression, anxiety, and alexithymia have shown significantly weaker reflection and monitoring skills than those with low levels (e.g., Bressi et al. 2017; Fonagy et al. 1996; Ladegaard et al. 2016). High levels of anxiety in particular have been found to be significantly related to poor accuracy when judging how well material has been learned (confidence judgments; Fonagy et al. 1996). To date, it is unclear to what extent weaker performance on metacognitive tasks is related to the presence of additional co-occurring conditions.

Currently, there is not enough evidence to determine which, if any, of these possibilities best explain the pattern of results found in studies of metacognition in autism. As such, it will be important that future research investigates the nature of the underlying processes that autistic individuals use to inform their metacognitive judgments, and whether these processes depend on the types of metacognitive tasks employed.

Future Directions and Implications

It is important to consider the implications of research exploring metacognitive abilities in autism. Crucially, metacognitive skills are trainable; studies suggest that the academic performance of students significantly improves following training in metacognitive skills. In fact, training in metacognition has been shown to improve academic and work place performance across all levels of cognitive ability (e.g., Perry et al. 2018). Thus, the study of metacognition in autism could have important implications for educational practice. Considering the high incidence of co-occurring conditions in autism and the fact that therapies aimed at alleviating mental health difficulties often rely on good metacognitive skills, metacognitive research could also have important implications for autistic mental health and wellbeing. Moreover, recent research has found metacognitive skills in autism to be strongly associated with social skills (Leung

et al. 2016). While the causal direction of this relationship is not yet clear, it does suggest that training in metacognitive skills has the potential to influence social-interaction proficiency in autism. Ultimately, future research in autism should aim to determine a clearer profile of metacognitive strengths and weaknesses. Identifying particular areas of metacognitive strengths and difficulties may inform autistic educational and training practices with an end focus of positively impacting academic and social skills in autism, as well as potentially increasing the tools autistic individuals have to improve their health and well-being.

association between metallothionein abnormalities and autism. Despite this lack of support, some scientists and clinicians have attempted to treat autism by increasing metallothionein function. However, no peer-reviewed clinical trials have provided any evidence to support this treatment (Owens et al. 2008).

Metallothionein

Madison Pilato
Neurodevelopmental and Behavioral Pediatrics,
University of Rochester Medical Center,
Rochester, NY, USA

Definition

Metallothioneins are proteins that bind metals, controlling the levels of these metals in the body and preventing toxic effects (Owens et al. 2008). Some hair and urine analysis studies have shown that levels of heavy metals are increased in children with autism (Owens et al. 2008). Animal studies have demonstrated that mice with dysfunctional metallothioneins are at increased risk for heavy metal (specifically, mercury) poisoning but do not show baseline behavioral sequelae. Additionally, there are natural differences in metallothionein genetics, which may lead to the creation of faulty metallothionein proteins, predisposing an individual to heavy metal sensitivity. The hypothesis that children with autism have faulty metallothionein proteins and are therefore more sensitive to metals from the environment and potentially vaccines has been proposed as an explanation for the cause of autism. However, there are no peer-reviewed studies showing an

Metaphoric Language

Maura Moyle and Claire Plowgian
Speech Pathology and Audiology, Marquette
University, Milwaukee, WI, USA

Synonyms

[Idiosyncratic language](#)

Definition

Individuals with autism spectrum disorders (ASD) may produce speech that appears to be irrelevant to the current communicative context. For example, Kanner (1946) described a child with ASD who would yell, “Don’t throw the dog off the balcony!” whenever he was about to throw something. His parents reported that several years earlier, they had been staying in a hotel with a balcony and warned

the child not to throw his stuffed toy dog over the railing. Kanner emphasized that this “metaphorical language” was not irrelevant or meaningless. Rather, individuals with ASD attach unique meanings to these “figures of speech” based on specific past experiences.

[Ritalin](#)

Definition

Methylphenidate: Methylphenidate is also a stimulant medication. Although it also enhances release and blocks reuptake of dopamine, it is less potent than the amphetamines. There are many preparations with methylphenidate including immediate-release compound in which the tablet is rapidly absorbed and the duration of action is approximately 4 h. When using the immediate-release compounds, it is likely that the dose will have to be repeated twice or even three times per day. There are also long-acting formulations marketed under several different trade names. These long-acting formulations do not have to be repeated throughout the day. However, various products may only come in particular strengths. Therefore, becoming familiar with the different brands of medications is important for using these long-acting formulations of methylphenidate in the clinic. Methylphenidate also comes in a transdermal skin patch. The skin patch can be worn for 8–9 h per day and replaced with a new patch each day. The skin patch comes in several strengths and may require some trial and error in that the oral dose of methylphenidate may not immediately translate to the dose of the skin patch. One drawback of the current skin patch preparations is their high cost.

The immediate-release formulation of methylphenidate was studied in a large-scale, multisite trial in children with autism spectrum disorders (Research Units on Pediatric Psychopharmacology 2005). The study included three doses of methylphenidate (low to high) and placebo in a crossover trial (each subject received the study treatments in random order under double-blind conditions). All active dose of methylphenidate was superior to placebo in this short-term study. In contrast to the benefits observed in typically developing children with attention deficit/hyperactivity disorder, however, in children with autism spectrum disorders who were hyperactive, impulsive, and distractible, the beneficial effects were modest. The study in children with autism spectrum disorders showed that doses that are well tolerated in typically developing children with attention deficit/hyperactivity disorder were less well tolerated in children with autism spectrum disorders. Intolerable adverse

effects included irritability, insomnia, loss of appetite, and increased stereotypic behavior. These results suggest that when treating children with autism spectrum disorders accompanied by hyperactivity and impulsiveness, the low-to-medium doses are likely to produce modest benefit. However, attempts to achieve a greater benefit by pushing the dose upward are likely to encounter dose-limiting adverse effects.

Mexico and Autism

Patricia Sánchez Lizardi¹ and Carlos Marcín Salazar²

¹School of Psychology, Universidad Panamericana, Mexico City, Mexico

²Clínica Mexicana de Autismo y Alteraciones del Desarrollo, A. C., Mexico City, Mexico

Historical Background

Public awareness of autism spectrum disorder (ASD) in Mexico can be traced back to the late 1970s when families affected by ASD began searching for places where their children could receive treatment. Given that fewer options for diagnosis and treatment existed in other states, most families headed to Mexico City. In the early 1970s, children with ASD were often

misdiagnosed and frequently placed in treatment in special education schools for children with other types of disabilities, thereby preventing them from receiving appropriate intervention.

In the following section, we cover the historical background of ASD in Mexico based on the firsthand experience of the second author, Dr. Carlos Marcín. Dr. Marcín has been active in attending to the needs of children and families affected by ASD for over 40 years, both as an academic and as a clinician.

First Phase: 1970–1990

Autism was first conceptualized as a psychiatric disorder by the National Ministry of Health and treated in Mexico City at the “Dr. Juan N. Navarro” Children’s Psychiatric Hospital, the only public institution treating children and adolescents with autism in the country at that time. Treatment offered was medical, from a psychodynamic perspective, which was the main theory in Mexico for explaining autism. Given the growing need for treatment, families organized to form *Centro Educativo Domus*, a nonprofit organization that began offering applied behavior analysis (ABA), which had been successful in the United States in teaching appropriate behaviors to individuals with autism (Lovaas et al. 1974; Lovaas 1987). Another effort worth mentioning was the opening of the *Center for Autism* at Universidad Intercontinental in Mexico City. This center was created with the support of the Japanese government. Dr. Tetsuo Ishi began providing communication-acceptance treatment. In 1983, at the same university, Dr. Marcín led the creation of a Master’s program in autism. Unfortunately, this program closed after graduating only one class.

In 1990, the Mexican Clinic for Autism and Developmental Disorders (Clínica Mexicana de Autismo y Alteraciones del Desarrollo, A.C., *CLIMA*) was founded by Dr. Marcín and a group of families that needed treatment for their children with autism. *CLIMA*, a nonprofit, private organization, began offering evidenced-based treatment for children, providing family counseling, and training professionals. *CLIMA*’s treatment model integrated elements of applied behavior analysis

(ABA), Treatment and Education of Autistic and Related Communication Handicapped Children (TEACCH), Picture Exchange Communication System (PECS), sensory integration therapy, and social skills training. A goal of the intervention was to promote children's educational and social inclusion as early as possible.

In 1990, *CLIMA* organized the first international meeting on autism in Mexico, *Autismo en el Mundo*, *Autismo en México*, with the participation of Dr. Bernard Rimland, from the San Diego Autism Research Institute. This 3-day meeting involved families and professionals and covered diagnostic, etiological, and treatment issues for people with autism. During his interventions, Dr. Rimland also confronted the psychodynamic idea, prominent in Mexico, of the "refrigerator mother" as the cause of autism, offering instead a possible neurodevelopmental explanation.

Second Phase: 2000–Present

During this phase, *CLIMA* has continued working to ensure the provision of evidence-based treatment, offering continuing education opportunities for professionals and families, and participating in research. In 2005, *CLIMA* organized a second conference on *Autismo en el Mundo*, *Autismo en México*. This time, the conference was also supported by Universidad Iberoamericana. This 2-day meeting had the participation of renowned speakers in the field of autism, such as Simon Baron-Cohen, Clara Lajonchere, and Matthew State, who expounded upon the most current research findings concerning genetic factors and theory of mind. In 2007, *CLIMA*, with the support of Autism Speaks and the Carlos Slim Health Foundation, organized a 3-day international meeting, *Autism Speaks to the World (El Autismo habla al Mundo)*. The meeting was free of charge for 2000 participants (families and professionals) and broadcasted online free of charge to about 30,000 more participants through the Mexican telecommunications company, Telmex. The meeting covered topics about early detection, neurological findings, evidence-based practices, genetic findings, learning and communication disorders in autism, and prevalence. Keynote speakers were from different countries and included Geraldine

Dawson, Eric Courchesne, Pat Levitt, Eric Fombonne, Sam Odom, Clara Lajonchere, Helen Tager-Flusberg, Ami Klin, and Andy Shih (United States); Tony Charman (Great Britain); Carlos Marcín (Mexico); and Cecilia Montiel (Venezuela).

An event of special importance in the history of autism in Mexico was the *Pan-American Autism Awareness Training Initiative (PAAATI)*. From 2009 to 2012, yearly meetings and workshops were held. The first two meetings focused on identifying the needs of Mexican and Latin American children with autism and their families in the home setting. Organizations supporting this initiative were *CLIMA*, Autism Speaks, American Pediatrics Association, Carlos Slim Health Foundation, and Miami University. The third meeting, in 2011, focused on family's burden and in training 70 professionals on ABA interventions. The training was given by Deborah Fein from the University of Connecticut and Lynn Cohen Brennan from Boston University. In 2012, the fourth meeting was focused on collecting information from families that led to the development of a *Manual for Intervention at Home* to be delivered to children with autism by their parents. This meeting was led by Wendy Stone, Inger Brooke, and Carlos Marcín. The motivation was principally that the *Manual* could be helpful to Spanish-speaking families in Latin America and the United States. Because of the PAAATI, in 2010, a national early detection campaign was carried out with the support of the Carlos Slim Health Foundation. Using *The Modified Checklist for Autism in Toddlers (M-CHAT)*, adapted to the Mexican culture, children at risk of autism were identified. A workshop for the families of these children was offered so that ABA intervention at home could be provided. The intervention was compiled on a manual, *The Programa de Intervención Temprana*, and distributed among families.

Over the years, nonprofit organizations have opened in many cities across Mexico. Many of them follow *CLIMA's* service model, but others do not clearly state the type of intervention they provide (http://www.educacionespecial.sep.gob.mx/pdf/doctos/6Boletin/Directorio_teleton.pdf).

Legal Issues, Mandates for Service

From 1970 to the mid-1980s, children with disabilities only received services from the Mexican health system, under the auspice of the General Health Law (Ley General de Salud). Services were provided in rehabilitation centers, psychiatric hospitals, and special education schools (in coordination with the educational system). However, the process of inclusion of students with special needs into the general education system began in the late 2000s. Specifically, in the case of autism, inclusion practices came later, perhaps because of the lack of awareness and epidemiological data about autism in Mexican children. A changing moment for the mandate of services to people with autism came on March 30, 2007, when Mexico, along with other countries, signed the Convention on the Rights of Persons with Disabilities (CRPD) at the United Nations (<https://www.un.org/development/desa/disabilities/convention-on-the-rights-of-persons-with-disabilities.html>). The agreement stated a commitment to avoid discriminating against people with disabilities, viewing them as persons with rights and creating the structure to increase inclusive practices at all levels of society. Mexico committed to report to the UN its progress toward this goal with the UN providing feedback about the progress obtained. Mexico's first report in April 2011 focused on the actions taken to provide rehabilitation to people with physical disabilities. In addition, in the 2010 census, data regarding the number of people with disabilities in Mexico began to be collected, indicating that the Mexican population with disabilities was similar to other countries, ranging between 6% and 9%. In this report, ASD was not included.

In 2011, the *General Law for the Inclusion of Persons with Disabilities* was approved by the Mexican Congress. The law stated that the state had to protect and ensure the human rights and fundamental freedoms of people with disabilities with the goal of their full inclusion in society. The law enunciated five disabilities but ignored ASD as one of them. This would provoke a reaction among families and advocates of ASD, who

argued and fought to have ASD included. This reaction resulted in the General Law for the Attention and Protection of People with Autism Spectrum Condition (see Social Policy and Current Controversies below).

In terms of the education of children with autism, it has been reported that, since 1993 when Mexico enacted a federal law to improve the education of people with disabilities, the Secretariat of Public Education (Secretaría de Educación Pública, SEP) has provided special education services to children with autism (Tuman et al. 2010; Harris and Barton 2016). Before 2015, services were provided by two programs, the Centers of Multiple Attention (Centros de Atención Múltiple, CAM) and the Units of Support Services for Regular Education (Unidades de Servicios de Apoyo a la Educación Regular, USAER). From 2015 to the present, services to educate people with disabilities have been provided in inclusive classrooms through the Unit for Special Education and Inclusive Education (Unidad de Educación Especial y Educación Inclusiva, UDEEI). However, most children with autism attending regular schools have a one-on-one aide, typically paid for by the family.

Overview of Current Treatments and Centers

Provision of services in Mexico is not uniform, and little intervention is provided through the National Ministry of Health or public institutions. According to the National Ministry of Health, about 10,000 children receive health services in its institutions, from which an estimate of 2400 diagnosed with ASD receive some level of monthly intervention (www.gob.mx/salud/prensa/139-deteccion-tardia-de-autismo-impide-acion-oportuna-a-estos-infantes). In 2016, the local government in Mexico City opened the *Clinic for Autism* (Clínica de Autismo, www.cdmx.gob.mx/vive-cdmx/post/clinica-de-autismo-de-la-cdmx) that offers diagnostic evaluation and intervention to families of low socioeconomic background.

Additionally, in 2016, the federal government opened the *Regional Center of Ixtapaluca* (Centro Regional de Ixtapaluca) to provide services to children with developmental disabilities and ASD in the State of Mexico. This Regional Center is 1 of 13 centers that provide services to children with neurodevelopmental disorders in the country, but only this one specializes in ASD (www.gob.mx/salud/prensa/nuevo-centro-regional-de-desarrollo-infantil-y-autismo-en-ixtapaluca). Other major public institutions offering services to children with autism are the *Children's Psychiatric Hospital* (www.sap.salud.gob.mx/principales/%C2%BFen-d%C3%B3nde-me-atiendo/hospital-psiqui%C3%A1trico-infantil-dr-juan-n-navarro.aspx), the nonprofit organization *Autismex* (www.autismex.iap.org.mx), and the *Integral Center for Mental Health* (Centro Integral de Salud Mental, Cisame, www.gob.mx/salud/documentos/centro-integral-de-salud-mental-df), which have serviced families of low socioeconomic background. These institutions are in Mexico City.

Despite the services these public institutions offer, most of the intervention for autism has been provided by private clinics or centers that have different approaches and philosophies (e.g., applied behavior analysis to psychoanalysis). Since specific requirements or criteria that these centers must meet are lacking, a wide array of treatment possibilities exists, but the quality of treatment is difficult to ascertain given that information about their intervention models is not readily available to the public. Most service providers have an undergraduate degree in psychology; some have received specific training in ASD at the few available options (see Overview of Training below), but many have been trained as apprentices of senior therapists.

There are a few private institutions that provide evidence-based services to people with autism. Many of them were created by groups of parents with children with autism and the professionals treating them. As mentioned before, *CLIMA*, founded in 1990 by Dr. Marcín and a few parents of children with ASD, is perhaps the most well-known institution to provide integral services to

families affected by ASD in Mexico. It has 20 affiliated clinics across Mexico. *CLIMA* offers comprehensive diagnostic evaluations and a psychoeducational program of 25 h/week. The service model includes the expertise of psychologists, speech/language pathologists, and occupational therapists. Some therapists of *CLIMA* received the introductory training of the Early Start Denver Model (ESDM, Rogers and Dawson 2009) in 2012, with two of them already completed the certification and two more currently in the process of obtaining it. This is relevant considering that in the whole country, there are only five therapists certified in the ESDM according to the most recent list (April 2018) of the University of California Davis, MIND Institute (http://www.ucdmc.ucdavis.edu/mindinstitute/research/esdm/pdf/esdm_certifiedtherapists.pdf). The clinic also offers a program that supervises the inclusion of children in regular schools with the support of a one-on-one aide. The clinic has also participated in research projects (e.g., Hedley et al. 2010; Elsabbagh et al. 2012; Fombonne et al. 2016) and in training of professionals through courses in association with institutions of higher education.

Another well-recognized center is the Domus Autism Institute (*Instituto de Autismo Domus*) that started offering services to families impacted by ASD in the 1980s. *Domus* offers diagnostic evaluations, therapeutic interventions, and educational inclusion as well as services for adults to become as independent as possible (www.institutodomus.org). The third largest private institution, *Centro Autismo Teletón*, opened in 2012 as a foundation supported by business groups and the media in Mexico. *Teletón* has compiled a directory including other small private centers that offer services to children with disabilities, including children with ASD, but their model of services is not publicly described or easily available (www.educacion.especial.sep.gob.mx/pdf/doctos/6Boletin/Directorio_teleton.pdf). Finally, *Iluminemos de Azul* is another nonprofit organization dedicated to creating awareness about autism in society so that people with autism and their families have a better quality of life.

Overview of Research Directions

Research addressing issues related to ASD is limited in Mexico. However, this is not much different from other research areas. In 2012, at the beginning of the current administration, it was promised that 1% of GDP would be invested into research programs and development by the end of June 2018. However, Mexico currently spends only 0.53% of its GDP in supporting research development, compared to the average of 2.38% of the OECD countries and far from the highest investing countries, Israel (4.25%) and Korea (4.23%) (<https://data.oecd.org/rd/gross-domestic-spending-on-r-d.htm>).

Despite limited support for research, several projects have been carried out, and few research programs are currently under way, varying in approach and sub-area of expertise. One of these projects evaluated the validity of using the Autism Detection in Early Childhood (ADEC) in Mexico. Its findings suggested this instrument could be used with confidence to screen for autism (Hedley et al. 2010). Another relevant study, funded by Autism Speaks, determined that the estimated prevalence of ASD in Mexico is 1 in 115 or 0.87% [95% CI (0.62, 1.1%)] (Fombonne et al. 2016). A preceding study, conducted by the same group, validated the use of John Constantino's Social Responsiveness Scale (SRS) with the Mexican population (Fombonne et al. 2012). Albores-Gallo et al. (2012) examined the validity of the M-CHAT (Robins et al. 1999) for use with Mexican population. In addition, Dr. Albores-Gallo, at the Children's Psychiatric Hospital, has a line of research devoted to studying ASD in children and adolescents and has reported the conclusion of six different projects (<https://sites.google.com/site/hpicomisioninvestigacion/desarrollo>). Furthermore, other projects about ASD have been completed within the same institution as a requirement to obtain a medical degree with a specialty in child and adolescent psychiatry (<https://sites.google.com/site/hpicomisioninvestigacion/psiquiatria-infantil-y-de-la-adolescencia>).

More recently, other studies have been published as a sign of an emergence of such

research programs in Mexico. For example, a study found that Mexican pediatricians could improve their knowledge about early signs of ASD in their practice so that proper referrals for comprehensive assessment by specialists could be completed and early intervention started (Zúñiga et al. 2017). This information has been shared with the Ministry of Health so that steps toward training pediatricians might be taken.

Within the educational setting and considering the international trends of inclusion, Sánchez Lizardi and Sohn McCormick (2016) surveyed general education teachers, K-12, to understand what their perspectives and needs were when educating students with ASD in their classrooms. This study found that teachers' primary concern was their lack or limited knowledge about ASD.

Perhaps the most ambitious of research programs is the *Consortium of Genomic Characterization of ASD in Mexican Population*. This consortium was formed in 2016 by Dr. Humberto Nicolini and includes nine academic, private clinics, public hospitals, and research institutions with the purpose of identifying the genes involved in ASD within the Mexican population. Presently, interviews and samples have been collected from a small number of families affected with ASD. Because academic institutions are part of the consortium, doctoral dissertations and Masters' theses are also in progress.

Overview of Training

Presently, there are no unified efforts for the training of teachers or health-related professionals about ASD in Mexico. Some of the centers mentioned above offer a variety of learning activities that range from lectures and short-term courses to 10-month certified courses. In particular, CLIMA offers a 10-month certified course in conjunction with the National Polytechnic Institute (Instituto Politécnico Nacional, IPN). Dr. Marcín has offered this type of certified courses in different states of Mexico and has trained approximately 3250 professionals in addition to offering workshops to about 8000 families in the last 28 years.

Treatment centers have invited international trainers in diagnostic instruments and interventions (e.g., Autismo Puebla www.autismopuebla.org), with professionals across Mexico earning these continuing education credits. Other opportunities for training have been national and international autism conferences, sponsored by different organizations (e.g., Carlos Slim Health Foundation, Health Ministry of Chiapas, and the National System for Integral Family Development of Yucatán). However, it is difficult to ascertain the implications of these learning opportunities on professional practice given that they are not officially regulated.

Social Policy and Current Controversies

Lay (2016) has closely followed the creation and controversies around the law pertinent to people with ASD. In 2014, an initiative to create a General Law for the Attention and Protection of People with Autism Spectrum Disorder was presented to the Mexican House of Representatives. The controversy was related to the term *disorder*, and it arose among families affected by ASD and advocates, who, from a human rights perspective, argued that this should be changed to the term *condition* because it was more socially inclusive and beyond a mere clinical presentation. Thus, on March 5, 2015, the Mexican House of Representatives approved the General Law for the Attention and Protection of People with Autism Spectrum Condition (http://www.diputados.gob.mx/LeyesBiblio/pdf/LGAPPCEA_270516.pdf). The Senate approved it 21 days later, being signed by the president and officially published on April 30, 2015. However, in June 1, 2015, the National Commission of Human Rights asked for an appeal of the law, arguing that some articles violated the International Convention on the Rights of Persons with Disabilities and that they were unconstitutional. After several months, in February of 2016, the Supreme Court declared unconstitutional only one of the articles and validated the remaining parts of the law.

Microcephaly

Itxaso Marti

Neuropediatrics, Hospital Universitario Donostia, San Sebastian, Spain

Synonyms

Microcephalic; Microcephalus; Nanocephaly

Definition

The term “microcephaly” is used to indicate a head circumference (HC) with two standard deviations (SD) below that expected for age, sex, and race. Some authors consider microcephaly when the HC is 3 SD below. A small skull suggests, in most cases, a small brain. Given that 55% of the brain is cortex, a small brain means less cerebral cortex, and it is associated with intellectual disability in approximately 30–50% of the cases. We distinguish two forms of microcephaly: primary and secondary. When it appears before the first 32 weeks of gestation, it is considered as primary microcephaly and when it appears after birth, it is considered as secondary microcephaly. Most neurons are generated during the first 21 weeks of gestation, and neuronal connections are generated after birth. Therefore, in cases of primary microcephaly, there is often a lack of neurons, whereas in the secondary cases, the initial neuronal production is usually normal, but few neural connections are produced, or there is subsequent neuronal death. The causes of both primary and secondary microcephaly may be genetic, secondary to prenatal infections or metabolic diseases, among others.

Micrographia

Giacomo Vivanti

A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, USA

Definition

Micrographia is abnormally small handwriting or handwriting that becomes progressively smaller and harder to read. Micrographia is a common feature of Parkinson's disease, possibly reflecting difficulties with scaling and controlling the amplitude of movement (Rao et al. 2003). Micrographia, however, can develop as a sign of focal neurological lesions that disrupt the cortico-subcortical loop involving the putamen, thalamus, premotor cortex, and sensorimotor cortex (Denes et al. 2005; Kim et al. 1998). Difficulties in handwriting have been documented in children with autism spectrum disorder including issues with legibility (Kushki et al. 2011), letter formation (Fuentes et al. 2009), and macrographia (Beversdorf et al. 2001; Johnson et al. 2013), but not micrographia.

Midazolam

Jonathan Kopel

Texas Tech University Health Sciences Center (TTUHSC), Lubbock, TX, USA

Synonyms

[Dormicum](#); [Versed](#)

Definition

With increasing numbers of Autism Spectrum Disorders (ASD) children, clinicians have investigated alternative pharmacological and behavioral interventions to minimize perioperative problems among ASD children

(Taghizadeh et al. 2015). Currently, clonidine, dexmedetomidine, midazolam, and ketamine remain the first-line premedication therapies for ASD patients undergoing surgery (Taghizadeh et al. 2015). Midazolam is a benzodiazepine medication used for *anesthesia, procedural sedation, trouble sleeping, and severe agitation*. Several case reports showed midazolam is an effective premedication for mild ASD cases and exhibits comparable efficacy to other administered benzodiazepines (Capp et al. 2010; Jo et al. 2017; Pisalchaiyong et al. 2005; Seo et al. 2014; Shah et al. 2009; Van Der Walt and Moran 2001). However, ASD patients administered midazolam experienced several side effects including: “emergence phenomenon, disorientation, sensory and perceptual illusions and vivid dreams in recovery, nausea and vomiting, nystagmus, hypersalivation, and occasionally laryngospasm” (Taghizadeh et al. 2015). Furthermore, one study showed 30% of ASD patients premedicated with midazolam remained uncooperative before surgery (Van Der Walt and Moran 2001). Thus, current guidelines suggest clinicians incorporate parents and simple behavioral strategies, such as providing comfort items, along with premedication to reduce anxiety and discomfort among ASD children before surgery. Further research is required to determine which combination of medication and behavioral techniques produce optimal outcomes among ASD children undergoing surgical operations

Midbrain

Alexander Westphal

Division of Law and Psychiatry, Yale Child Study Center, Yale School of Medicine, New Haven, CT, USA

Synonyms

Mesencephalon

Definition

The midbrain is a component of the brain stem that plays a role in a number of central nervous system functions. It contains the substantia nigra, which has an important role in motor function. It also plays a role in vision, hearing, and arousal. Gaffney et al. (1998) found that the entire brain

stem to be significantly smaller in a group with autism. Other groups have replicated the finding and extended it to the midbrain in particular. Hashimoto et al. (1992) found that the midbrain and pons (another component of the brain stem) were significantly smaller in a group with autism in comparison to a control group. Furthermore, several studies have found functional abnormalities in the brain stems of subjects with autism (Maziade et al. 2000; Thivierge et al. 1990).

[Midbrain raphe nuclei](#); [Nuclei of raphe](#); [Raphe nuclei](#)

Definition

“Midbrain raphe” refers to two nuclei found in the reticular formation of the midbrain: the superior central nucleus and dorsal raphe nucleus. Other raphe nuclei are also found in the medulla and pontine reticular formations. The common element between all raphe nuclei is that they form a seam, or ridge, along the medial aspect of the brain stem, making up the most medial aspect of the reticular formation, a phylogenetically ancient part of the brain. The primary purpose of all raphe nuclei appears to be to release the neurotransmitter serotonin to other areas of the brain, including areas responsible for social information processing. They are also thought to play a fundamental role in regulating circadian rhythm (For a discussion of the role of serotonin in autism, please see the *serotonin* section of the encyclopedia. For a more general discussion of the midbrain, please see the *midbrain* section of the encyclopedia.)

Milestone

Danielle Geno Kent

The College of Arts and Sciences, The University of Vermont, Burlington, VT, USA

Synonyms

Developmental milestones; Indicator; Marker

Definition

Skills that are indicative of development. Examples are taking a first step, smiling for the first time, and waving “bye-bye.” Children reach milestones in how they play, speak, learn, behave, and move (Center for Disease Control [CDC] 2010). There is a standard pattern and age range for how and when most children achieve these milestones. Children with autism are typically delayed in their acquisition of communicative and social developmental milestones and also in their development of skills such as using eating utensils, drawing, dancing, rhythm, and music (Jones and Prior 1985).

Milieu Teaching

Andrea McDuffie

MIND Institute University of California-Davis, Sacramento, CA, USA

Definition

Milieu teaching (Hart and Risley 1975) includes a group of procedures, derived from the behaviorist tradition, that were developed to teach language skills to children by embedding learning opportunities within the child’s everyday (i.e., natural) environment and by taking advantage of a child’s interest in and motivation to gain access to materials. According to Goldstein (2002), incidental teaching represents the key component of milieu teaching. Incidental teaching episodes begin with spontaneous child-initiated communication acts as the child attempts to gain access to preferred materials, objects, or events within the natural environment. These child communication acts serve the pragmatic function of requesting (or manding). In addition to incidental teaching, two other well-known milieu language teaching procedures (described below) are mand model and time delay.

Because they are embedded in the natural environment, milieu language teaching procedures are often taught to parents who can then incorporate milieu language procedures into the child’s everyday routines and activities.

There are now many variants of the milieu teaching approach including prelinguistic milieu teaching, which focuses on teaching preverbal children to use nonverbal communication skills such as gestures, eye gaze, and vocalization; and enhanced milieu teaching, a more comprehensive approach to naturalistic language intervention, that includes environmental arrangement, responsive interaction techniques, and milieu teaching procedures.

According to Gilbert (2008), the following components are characteristic of milieu teaching:

1. Training in everyday environments
2. Arranging the environment to promote spontaneous requesting by the child

3. Offering preferred toys and activities to reinforce child communication
4. Building predictable turn-taking routines
5. Use of time delay (i.e., expectant waiting) to encourage communication
6. Waiting for the child to initiate by gesturing or indicating interest in an object or activity
7. Providing models of more advanced communication following a child initiation
8. Rewarding communication with access to the desired object/activity rather than unrelated reinforcers

Historical Background

Classic behavioral approaches to early language intervention made use of imitation procedures and tangible rewards for imitation. These methods have several drawbacks including communication that is passive or prompt dependent or which does not generalize to contexts outside of those in which the communicative behavior was taught. In addition, children who have not yet acquired the understanding that communicative bids can be used to affect the behavior of other people (i.e., who do not understand the instrumental function of communication as a means to a desired end) may have difficulty acquiring basic communication skills.

In response to these drawbacks of discrete trial interventions, behavioral interventionists began to develop methods that were based upon the strengths of behavioral programming (e.g., predictable structure, use of task analysis, attention to antecedents and consequences of behavior). These methods addressed the need to establish basic communicative behavior and to generalize communicative acts beyond the training setting. These developments also included the use of the natural environment as the context for learning, planning of contingencies carefully engineered to elicit spontaneous communicative acts that could be shaped toward more conventional and functional language, and the inclusion of parents as intervention agents.

Rationale or Underlying Theory

The rationale that led to the emergence of milieu teaching approaches is that it is important for children to learn to communicate within the everyday context within which their communication behaviors will be used. In addition, by arranging the environment to provide objects, actions, and events in which children have an interest, the child will be motivated to direct a request for access to the desired object or activity to the communicative partner who can then model more advanced and conventional forms of communication.

Goals and Objectives

The broad goal of milieu teaching is to increase the child's use of specific requesting behaviors. Related goals include teaching related grammatical forms and vocabulary. According to Hancock and Kaiser (2007), milieu teaching emphasizes reciprocity, turn taking, following the child's lead, meaningful and contingent feedback for child communication, and expansion of child utterances to model more advanced forms.

Treatment Participants

Responsive education/prelinguistic milieu teaching is designed for children at developmental levels between 12 and 18 months who have not yet become clear and frequent communicators. If children use more than 10 words or signs, or understand more than 75 words, then they should be enrolled in an intervention that places more of an emphasis on expressive vocabulary. Children for whom RE/PMT is appropriate should produce less than two acts of intentional communication per minute during play interactions with a caregiver.

Children enrolled in enhanced milieu teaching should be verbally imitative, have at least 10 expressive vocabulary words, and should have a mean utterance length of 1.0–3.5 words.

Treatment Procedures

Incidental teaching, time delay, and mand modeling have been identified as major components of the milieu language teaching procedure.

In the mand-model procedure, the teacher, clinician, or parent arranges the environment to include objects/actions/events that the child is motivated to request access to. When the child approaches the materials, the adult provides a mand, asking: "What do you want?" If this question elicits the child's production of a word or word approximation, the adult expands by providing a semantic or grammatically more advanced version of the child's production. If the child does not respond to the mand, the clinician provides a model: Say, I want truck. If the child does not respond, the teacher provides one more model and provides the child with access to the desired material.

The time delay procedure is a prompt fading strategy used to encourage children to use vocabulary that they do know, but may not frequently produce spontaneously. Time delay is similar to "fill in the blank." Again, desired materials are available to the child. The teacher holds an item (e.g., a puzzle piece of a cow) and says, "I want the _____."

Incidental teaching is a technique in which the adult uses child initiations during ongoing activities to provide language input. Incidental teaching requires that the environment be arranged to include materials and activities that are highly motivating to the child such that the child will initiate to gain access to the materials. Incidental teaching is child-directed in that the adult follows the child's lead and allows the child's current focus of interest to guide the teaching episodes.

Efficacy Information

According to the American Speech-Language-Hearing Association, there is a large body of empirical support for more contemporary behavioral approaches using naturalistic teaching methods that demonstrate efficacy for teaching not only speech and language but also

communication. The following specific intervention strategies have been found to promote initiation and generalization: arrange the environment to provide opportunities for communicating with preferred materials, encourage child initiations and follow the child's attentional focus and interest, intersperse preferred and nonpreferred activities, use embedded instruction in the natural environment, offer choices and encourage choice making, use natural reinforcers that follow what the child is trying to communicate, and use of time delay.

There are only a few studies, all using single-subject design, that have compared traditional discrete trial with naturalistic behavioral approaches. These studies have reported that naturalistic approaches are more effective at leading to generalization of language gains to natural contexts.

Outcome Measurement

Outcome measures used in studies of milieu teaching will typically consist of measures of the rate or frequency of child nonverbal or verbal communication acts, measures of utterance length (mean length of utterance in words), measures of use of grammatical morphemes (mean length of utterance in morphemes), and vocabulary use (lexical diversity, number of different words). Other measures may include parent use of targeted strategies or number of milieu teaching episodes.

Qualifications of Treatment Providers

Individuals who teach parents must have skills in the delivery of milieu teaching procedures but must also have skills in interacting with parents in ways that support parent learning. Professionals must have skills in providing coaching and feedback to parents and must be able to model desired parent behaviors within the context of a parent-child interaction without disrupting the interaction or overwhelming the parent.

Military Families with Children with Autism

Jennifer M. D. Kremkow

Department of Communication Sciences and Disorders, Elmhurst College, Elmhurst, IL, USA

Definition

Military families with children with autism are a subgroup of families with children with autism who have at least one member serving in the Armed Forces. The service members of military families may enlist with any one of several branches of the Armed Forces including the Air Force, Army, Coast Guard (during national emergencies or wartime situations), Marine Corps, and Navy (Blaisure et al. 2012). The service members of military families may be active duty, reserve, or National Guard members. Active duty members are full-time service men and women, which also requires their families to be full-time military families. Reserve and National Guard members are part-time forces, trained and ready if they are called upon to serve under command of the President or state governor, respectively (Blaisure et al. 2012). Since Reservists and National Guard members are part-time, their families are also part-time military families, frequently living in civilian communities with limited access to military supports if their service member is called for duty.

Since military families with children with autism are members of both the autism community and the military community, they have shared characteristics with both groups. For example, as members of the autism community, military families with children with autism share the experience of having a child with autism, service availability issues, and additional stress in the family. Children with autism may have a different constellation of symptoms from two categories – social interaction and communication and restricted and/or repetitive behavior (APA 2013). These characteristics may include difficulty with social interaction, insistence on sameness,

restricted interests, and limited and/or delayed communication (Barbaro and Dissanayake 2009), requiring intervention from several different professionals. Parents of children with autism have long reported difficulty finding the services their child with autism needs to improve a variety of impairments (Kohler 1999). As a result of challenging behavior from the child with autism, difficulty finding services, and other stressors, parents of children with autism have reported higher levels of stress than parents of neurotypical (e.g., typically developing) children or children with other developmental disabilities (Hayes and Watson 2013).

As members of the military community, military families with children with autism also share a common set of characteristics with military families, distinguishing them from civilian families. Segal (1986) described these characteristics as family separations (e.g., deployment), frequent relocations to military installations around the United States or overseas, and dangerous work environments. Some civilian families may experience these events on occasion; however, only military families experience all three characteristics on a routine basis. For example, a parent who works for an international company may travel overseas for meetings, resulting in temporary separation, but would likely not be in a dangerous environment while doing so. In contrast, military families may be separated from their service member multiple times per year for training or combat while their service member is at risk of injury.

This entry is divided into three sections. First, a brief history of the military and views of military families is provided for context of the culture surrounding military families with children with autism. Second, current knowledge related to military families with children with autism is summarized with comparisons to civilian families with children with autism and other military families. Finally, future directions for military families with children with autism are presented.

Historical Background

Prior to the start of an all-volunteer force in the early 1970s, most soldiers were not married and

had not yet started families. In fact, an old adage in military communities was “if the military wanted you to have a wife, they would have issued you one,” implying the military’s sole focus on the service member. However, with the start of an all-volunteer force in 1973, the demographics of the Armed Forces began to change. Service members were now more likely to have a spouse and children than they were before 1973. In 2015, over half (50.5%) of all service members were married and nearly half (41%) had at least one child, the majority of children between the ages of 0 and 5 years (Department of Defense [DoD] 2015). Military family members, also called military dependents, outnumber the service members by over 600,000 (DoD 2015). Military dependents were becoming a part of the military community the DoD could not overlook.

With the increase in service members with families, the DoD began to recognize the importance of military families for military operations, satisfaction with the military way of life, and, ultimately, retention of the service member in the Armed Forces. In 1985, the Military Family Act was passed to establish a government commitment to helping military families for the first time. The military started to view mission readiness (i.e., the ability of the service member to perform duties), as related to family readiness (i.e., the ability of the family to successfully navigate the demands of military life) (National Military Families Association [NMFA] 2006). The family members of service members needed to be taken care of if the service member was to focus on the mission and have support from the family to remain in the military. In response to shifting demographics and recognition of family readiness, the military created informal and formal support systems for families (Albano 1993). For example, each service has a family assistance center to help military families with different military lifestyle-related concerns such as relocation preparation and insurance.

Although military families are generally viewed as resilient to stressors and adaptable in new or difficult circumstances (Blaisure et al. 2012), the recent wars, military operations, and deployments have taken a toll on military families. Since 2011, there have been several

missions in the Middle East (e.g., Operation Enduring Freedom) requiring over two million service members from active duty, reserve, and National Guard components to serve overseas. In a recent survey, Blue Star Families (2016) found 72% of military spouses reported the current climate of military operations is too stressful. Military families have endured a long period of mobilization, testing their resilience, especially those families with additional stressors not related to the military lifestyle.

Current Knowledge

Despite over 1.7 million children considered military dependents (DoD 2015), research on children in military families, particularly those with autism, is limited. Currently, there are private organization reports and surveys (e.g., OAR 2010; Blue Star Families 2013), government reports (e.g., Ohio State University Project Team 2011), and a few peer-reviewed articles (e.g., Davis and Finke 2015; Freuler and Baranek 2016) to aid professionals and military families in supporting military children with ASD. Most of the research for military families with children with autism has been related to deployments and relocations, two of the main characteristics of military families.

Deployments

A deployment refers to a time when the service member is relocated for a period of time (e.g., a few weeks or multiple months) for a military purpose such as wartime needs or training exercises. When a service member deploys, the family must to adapt to their absence. Members take on new roles and responsibilities once performed by the service member, frequently resulting in changes to the family routine and an increase in family stress as the family learns to adjust (Drummet et al. 2003). This may be particularly true for military families with children with autism, given the amount of care often required for a child with autism. Civilian families with children with autism have reported the numerous responsibilities required to care for a child with autism (Myers et al. 2009), even without the added challenge of losing a parent for a few weeks to a few months. Interviews with military spouses with

children with autism confirmed they experience an increase in emotional stress during deployments (Davis and Finke 2015). Many spouses also reported feeling very isolated in their community as many are away from friends and family and without the help of their deployed spouse (Davis and Finke 2015; Freuler and Baranek 2016).

Children may have difficulty adjusting to the absence of their service member parent. A systematic review by Alfano et al. (2016) found young children express greater externalizing behavior (e.g., temper tantrums, defiance) when they have a deployed parent. Studies with older children reported mixed evidence of deployment effects, but some outcomes such as mental health diagnoses, stress, and mood or behavior disorders were more common when a parent was deployed (Alfano et al. 2016). Military spouses have reported similar emotional and behavioral differences in their children with autism when their service member is deployed (Davis and Finke 2015; Freuler and Baranek 2016). Some spouses have commented on their child's emotional withdrawal during deployments and the difficulty the child has in understanding why their parent is not at home (Davis and Finke 2015). Other spouses have noticed an increase in frequency and severity of autism symptoms during deployments (Davis and Finke 2015).

Relocation

When the military needs a service member at another installation, they issue a "permanent change of station" (PCS) and require the family to relocate to a new area. Finding medical and therapeutic care after a relocation is challenging for military families with a child with autism. Each time the family relocates, they must find an assortment of interventions to address the wide range of symptoms associated with autism. For example, parents of children with autism have reported working with an average of approximately seven different professionals over six months (Kohler 1999). Military families with children with autism have reported delays in obtaining therapeutic services, limited therapeutic or medical providers in their area, lack of service continuity, and lack of therapeutic service quality (Davis and Finke 2015; Davis et al. 2016; Freuler

and Baranek 2016). Specifically, the majority of 189 military spouses in a survey reported only some access to interventions their child with ASD required, delays in access to interventions, limited access to assistive technologies when they were needed, difficulties finding physicians near their homes, and inadequate continuity of interventions across locations (Davis et al. 2016). Civilian families with children with autism have also reported limited availability and accessibility of therapeutic services for their child with autism and dissatisfaction with the quality of some of those services as well (Kohler 1999). However, in most circumstances, military families are required to relocate more often than civilian families, compounding service availability issues.

Along with finding medical and therapeutic services, military families must find and enroll their child in a new school. Military children switch schools an average of six to nine times between kindergarten and 12th grade, causing disruption in educational programming (Ohio State University Project Team 2011). Changing schools requires transferring student files, completing paperwork, and learning about the receiving school's requirements. Interviews with school liaisons for the Marine Corps indicated school transitions as the most common and most severe problem for military families related to education (Aronson and Perkins 2013).

Given the number of school professionals children with autism may work with on a weekly basis, military families with children with autism may have even greater challenges related to school transitions after relocations. Military families with children with autism have commented on the lack of therapeutic service continuity between schools as it relates to the implementation of a child's IEP (Davis and Finke 2015; Davis et al. 2016; Freuler and Baranek 2016). Many also felt dissatisfied with the quality of the services provided by the school, some believing their options for legal recourse were limited due to their transitory lifestyle (Davis and Finke 2015). Similarly, civilian families with children with ASD have reported worries about transitioning between schools (Parsons et al. 2009), without the added stress of multiple required relocations during the child's school career.

Frequent relocation may increase a child's risk of emotional and/or behavioral distress. Data from a national health interview survey indicated increased family mobility as a risk to children's emotional and behavioral health and education, even after controlling for other variables (Simpson and Fowler 1994). Evidence with military children and relocation effects are mixed, with some studies supporting positive outcomes and others finding negative outcomes for the military children (Milburn and Lightfoot 2013). The negative impacts of relocation on military children with autism may be more pronounced given common symptoms of autism such as anxiety comorbidity, resistance to change, difficulty with social interaction, and challenging behavior (Barbaro and Dissanayake 2009). Military spouses reported their children with autism demonstrated an increase in challenging behaviors, such as more aggression and temper tantrums, after relocation (Davis and Finke 2015; Freuler and Baranek 2016). Military spouses also stated their child with autism was more anxious after relocation, particularly until the family reestablishes a routine (Davis and Finke 2015). Some military spouses commented on the difficulty their child with autism had establishing new friend support in the new school and community (Davis and Finke 2015).

Military families with children with autism may be even more at risk for stress related problems. Current research has indicated military spouses encounter greater amounts of stress following a relocation than when the family is settled (Davis and Finke 2015). Similarly, civilian parents of children with autism have reported greater amounts of stress than parents of neurotypical children or children with other developmental disorders (Hayes and Watson 2013). Therefore, military families with children with autism are likely starting at a higher baseline of stress than other military families and are likely a higher risk for stress and problems related to stress.

Military Supports for Families with Children with Special Needs

Recently, the DoD has sought to reduce some of the challenges military families with children, including those with special needs, encounter as a

result of being in the military. For example, as a way to alleviate some of the challenges related to school transitioning, the DoD encouraged states to sign the MICCC (2011). The MICCC (2011) is an agreement signed by all 50 states to enhance educational opportunity for military children by reducing barriers to school enrollment, placement and eligibility for classes, and graduation. Another school-based program is the school liaison programs operated by each service to help military families solve issues related to the military and schools (DODEA 2014). The DoD has updated their websites such as Military One Source to be more user-friendly and have added sections containing information specific to military families with children with special needs. They have also established a program called the Exceptional Family Members Program (EFMP), independently operated by each military service to help ensure families are relocated to an installation near resources required to meet the family member's special needs (OAR 2010). EFMP offices may also provide other supports for the families; however, these additional supports are not required and vary in scope and quantity by branch and installation (OAR 2010). The DoD created the Extended Care Health Option (ECHO) program to help provide additional financial support for the medical needs of families with members with special needs; however, families must enroll after each move (OAR 2010). While these supports by the DoD are helpful, they do not address all of the needs for autism and military issues. Further, military families commented the problems did not meet their expectations and are inconsistent (Blue Star Families 2013). Additional research needs to be completed to determine which supports are required and how they should be implemented.

Future Directions

Military families with children with autism report several challenges they encounter as a result of having a child with autism and being a part of the military lifestyle. The challenges reported are similar to those faced by other military families and other families with children with autism; however,

it is the dual membership in both communities susceptible to difficulties that exacerbates the challenges military families with children with autism face. Given the lack of peer-reviewed research in this area, policymakers, professionals, military personnel, and researchers have little information to guide them when developing policies and programs to support these families. Additional research should be completed to help fully address the challenges military families with children with autism experience. Further, it is possible supports developed for military families with children with autism may be useful for civilian families as there are parallels between the two populations. Examples of future research directions include the following:

1. Experiences of male spouses with children with autism
2. Experiences of Reservist and National Guard families with children with autism
3. Concomitant family issues (e.g., a parent with post-traumatic stress disorder) and a child with autism
4. Programs and supports helpful to military families with children with autism
5. Medical and therapeutic professionals' knowledge of military families and their culture

Miller Assessment for Preschoolers (MAP)

Lucy Jane Miller^{1,2} and Sarah A. Schoen³

¹STAR Institute for Sensory Processing Disorder, Greenwood Village, CO, USA

²Department of Pediatrics, University of Colorado Denver, Denver, CO, USA

³Sensory Processing Disorder Foundation, Rocky Mountain University of Health Professions, Denver, CO, USA

Description

The Miller Assessment for Preschoolers (MAP) is designed to evaluate the developmental status of children aged 2 years 9 months to 5 years 8 months

across a broad range of areas including behavioral, motor, and cognitive functioning. The MAP test items are categorized into five performance indices. The foundations and coordination indices assess sensory motor abilities involving basic gross and fine motor tasks, awareness of sensations, and oral motor skills. The verbal and nonverbal indices assess cognitive skills required for language development, problem solving, memory, and perception. And the complex task performance index measures sensorimotor abilities in conjunction with cognitive abilities that require the interpretation of visual-spatial information. For children with severe developmental problems, the MAP can be used to provide a developmental overview and to clarify strengths and weaknesses. The MAP may be administered and scored by a wide range of professionals including psychologists, occupational therapists, physical therapists, speech pathologists, nurses, or special education teachers. Scores are obtained through direct testing, and subjective aspects of performance are included in the behavior during testing checklist as well as in supplemental observations that do not contribute to a child's total score. Total scores and performance index scores are expressed in percentile ranks. Item percentiles can be used to interpret the performance of at-risk or borderline cases.

Historical Background

The Miller Assessment for Preschooler was the culmination of 10 years of research involving 4,000 children and 800 test items. Each item was field tested with small samples of preschoolers, and 530 items were chosen for the MAP tryout edition. It is from this sample that the 27 items that constitute the MAP were selected. The MAP was first published in 1982 and then revised in 1988. The theoretical information that contributed to the development of the MAP comes from a broad range of literature in child development, education, psychology, language development, physical and occupational therapy, and medicine.

Psychometric Data

The MAP was standardized on a sample of 1,200 preschoolers, representing all nine continental geographic regions of the United States. Approximately, equal numbers of children in each region were tested, and the sample was stratified by age, sex, race, size of residential community, and socioeconomic factors.

Reliability

Reliability of the MAP was determined using interrater agreement, test-retest reliability, and internal consistency of the total test.

Interrater reliability was calculated on 40 children. Correlation coefficients were calculated on a sample of 40 children who participated in the interrater reliability study. Scores ranged from .84 to .99 for the total test and the performance indices and are suggestive of a high level of interrater agreement.

Test-retest reliability was calculated on a group of 81 children randomly selected from the standardization sample. The two tests were administered between 1 and 4 weeks after initial testing. Retest stability is reported in percentages and ranged from 72% to 94% for the total score and the five performance indices.

Internal reliability was calculated from the item raw scores for the total sample using split half method and the average item to test correction. Both methods produced internal consistency values around .80.

Validity

Three methods were used to support the validity of the MAP: content, criterion-related, and construct validity.

Content validity of the items was established by experts from a number of specialty areas who were asked to rate the content validity within their fields of expertise. A content specifications by item table supports the content validity of the test.

Criterion-related validity was established using concurrent and predictive validity. MAP scores were correlated with one of the four standardized instruments including the Wechsler Preschool and

Primary Scale of Intelligence (WPPSI), the Illinois Test of Psycholinguistic Abilities (ITPA), the Southern California Sensory Integration Tests (SCSIT), and the Denver Developmental Screening Test (DDST). Correlations of the complex task index and the WPPSI verbal and performance IQ approached statistical significance. Correlations were significant for the ITPA and the MAP total score, the coordination index, and the nonverbal index. One significant correlation was found between the MAP foundation index and the SCSIT score. In comparison to the DDST, 72% of the sample was similarly grouped by both instruments; however, the MAP identified 24% more children in the at-risk categories.

Evidence of predictive validity was obtained from a study of children tested 4 years after initial testing with the MAP. Results suggest that performance obtained on the MAP in the preschool years is predictive of intelligence, motor skill acquisition, and school achievement 4 years later.

Clinical Uses

The MAP may be administered and scored by a wide range of professionals including psychologists, occupational therapists, physical therapists, speech pathologists, nurses, or special education teachers. The purpose of the MAP is to identify developmentally delayed preschool children who need further evaluation and to provide a comprehensive structure clinical framework for identifying a child's strengths and weaknesses. The intent is to identify difficulties in children in the preschool age group (that typically go undiagnosed) that cause them to fall behind their peers in one or more areas of development. The MAP can also be used with children who have more severe developmental problems to provide a developmental overview or strengths and weaknesses when comprehensive standardized evaluations cannot be administered.

The MAP has been translated into Hebrew and Japanese. Studies reflect characterization of clinical populations as well as use as an outcome measure in treatment effectiveness research.

Miller Function and Participation Scales

Sarah A. Schoen
Sensory Processing Disorder Foundation, Rocky Mountain University of Health Professions,
Denver, CO, USA

Synonyms

M-FUN

Description

The Miller Function and Participation Scales (M-FUN) is a developmental assessment for children ages 2.6–7.11, designed to assist therapists in determining how a child's motor capacities affect participation in home and school environments. Based on the World Health Organization's International Classification of Function, Disability and Health (ICF; WHO 2001), the M-FUN addresses the mandate of occupational therapists to evaluate the whole child and determine how a child's motor problems might be affecting his or her functional abilities. The scales consist of a performance component, which includes workbook activities to tap visual motor abilities and play-based activities that tap gross and fine motor abilities. The performance component is comprised of three subscales: gross motor, fine motor, and visual motor. In addition, there is a participation component, which consists of three observation checklists that rate a child's participation at home, school, and during the testing session. Among the abilities

examined in the M-FUN observation checklists are mobility, postural control, sensory discrimination and modulation, social skills and communication, object manipulation, and participation in daily routines.

Several indicators of a child's performance can be derived from the M-FUN including standard scores, percentile ranks, and age equivalents for each subscale. Criterion-referenced scores are derived for home observation, classroom observation, and test observation checklists. The scales can be used to determine if a child has a developmental delay, or for children older than 7.11 years who have known motor delays, the test can be used to measure progress or to plan treatment. Unique to the M-FUN is the Neurological Foundations Profile, which facilitates the identification of underlying impairments affecting the child's ability to perform tasks and serves as a guide for treatment planning. Additionally, the M-FUN provides information about growth in the child's visual motor, fine motor, and gross motor abilities. Following intervention, the child can be retested using the M-FUN, and progress scored can be derived that reflects the acquisition of new skills even if he or she is not progressing at the same rate as age-ability peers.

Historical Background

The M-Fun was developed out of the need for a functional motor evaluation of skills and abilities that underlie participation in school. Based on the model from the ICF (WHO 2001) and OT Practice Framework (AOTA 2002), the M-FUN employs a competency model rather than a deficit model to assess children.

Psychometric Data

Normative data was collected from over 400 children from four geographic regions of the United States (West, South, North Central, and Northeast). The standardization sample closely matches the demographic characteristics of children ages 2.6–7.11 by sex, race/ethnicity, and

parent education level reported the 2002 United States census. The standardization sample also included children in each age group (5–7% of total) who were diagnosed with a motor delay or impairment.

The reliability of the M-FUN was examined using test-retest reliability, internal consistency, and interrater reliability. Retest of 27 children from the standardization sample was conducted with 0–21 days of initial testing. Moderately high reliability was found across time for all ages with scores ranging from .77 to .82. Internal consistency reliability supports the homogeneity of the items in the scale with the average reliability coefficients ranging from .85 for the visual motor subscale to .90 for the fine motor subscale and .92 for the gross motor subscale. Reliability coefficients for the clinical group on each subscale were similar to those reported for the normative sample. In addition, reliability coefficients for all three observation checklists were excellent, ranging from .87 to .98. Interrater reliability was computed for 29 children with the average decision agreement 93–96% for each subscale.

Validity data was collected for test content, internal structure, relationship to other variables, and diagnostic accuracy.

Content validity was based on ICF, the OT Practice Framework, a review of the literature, and focus group experts. The internal structure was analyzed by examining patterns of scaled score intercorrelations. Coefficients were between .47 and .55 suggesting that each subscale measures a different motor construct/ability. Concurrently validity was examined in order to determine the M-FUN's relatedness with other instruments designed to measure similar constructs. One study compared scores on the Miller Assessment for Preschoolers (MAP) to scores on the M-FUN in a sample of 15 children. Correlations ranged from .47 to .83 suggesting that the two tests supply complementary information about a child's abilities. A study of discriminant validity revealed that the M-FUN subscales discriminate between children with clinically diagnosed delays and those who are typically developing at a meaningful and statistically significant level. Classification

analysis to assess the clinical utility of the M-FUN produced moderate to excellent sensitivity and specificity. For cutoff scores of 1 standard deviation below the mean, the sensitivity was between .69 and .89, and the specificity was between .80 and 1.00.

Clinical Uses

The M-FUN may be administered by a variety of qualified professional including occupational therapists, physical therapists, special education or adaptive physical education specialists, and early childhood interventionists who are interested in determining how a child's motor abilities affect their participation in home and school. Examiners should have experience in test administration, scoring, and interpretation, as well as knowledge of sensory processing and motor development in preschool and school-aged children.

The M-FUN can be used for a variety of purposes:

- To determine a child's eligibility for intervention services to address gross motor, fine motor, and visual motor delays
- To document delays in motor development (gross motor, fine motor, visual motor)
- To determine motor readiness/preparedness for school – strengths and needs in the area of motor abilities that may impact on the child's ability to participate fully in school and home routines
- To make recommendations for optimizing the child's functioning at school and home (least restrictive environment)
- To assist in the development of treatment planning through use of the neurological foundations profile
- To identify underlying neuromotor deficits affecting functional abilities – to identify fine motor, visual motor, and gross motor skill areas that might affect a child's school success

To measure progress over time following a course of intervention

Mindblindness

Marjorie Solomon
Department of Psychiatry and Behavioral
Sciences, UC Davis M.I.N.D. Institute,
Sacramento, CA, USA

Definition

“Mindblindness” is a term coined by autism researcher Simon Baron-Cohen (1990). It also is the title of the essay containing work from his doctoral dissertation (Baron-Cohen 1997). In that essay, Baron-Cohen theorized that humans have evolved to be able to “mindread” or to effortlessly, automatically, and unconsciously assess the behavior of others. This is critical because mindreading forms the basis of the ability to successfully engage in social interactions requiring the minute-by-minute interpretation and prediction of the behavior of one’s interaction partners. Baron-Cohen goes on to propose that persons with autism have a selective impairment in mindreading.

The concept of mindblindness is rooted in the fields of both evolutionary biology and cognitive science. It is Baron-Cohen’s contention that natural selection favored species and individuals from those species with greater social intelligence

which included mindreading abilities. Mindreading abilities enabled primates to cohesively bond together in organized social hierarchies to achieve common goals. Those who were more adept at playing social chess through excellent mindreading skills (forward planning, plotting, counterplotting, strategic problem solving to achieve one’s goals) ended up at the top of such social hierarchies. Given the importance of mindreading abilities to survival, in this view, such abilities are believed to be a discrete component of cognition or a “module.”

The human mindreading system is thought to have four separate components. The first – the intentionality detector (ID) – is a perceptual device that interprets approach and avoidance in terms of goals and desires. For example, it enables one to interpret the motion of a mouse toward cheese as reflecting the mouse’s desire to eat. ID is the first mechanism human infants use. It can be cued by all forms of sensory input (i.e., seeing or hearing something). The second mechanism is the eye direction detector (EDD), which works through the visual system and computes whether eye-like stimuli are directed toward or away from something, including whether the eyes are directed at the organism itself or toward another organism. The third component – the shared attention mechanism (SAM) – builds triadic representations which specify relations among the agent, the self, and another object or agent. For example, the SAM would compute that Johnny and I are both looking at the cheese (or mom). Finally, the theory of mind mechanism (TOMM) is a system for inferring the full range of mental states from behavior or for employing a “theory of mind.” Theory of mind is a shorthand term for the capacity to attribute mental states to oneself and others and to interpret behavior in terms of mental states.

Mindfulness-based therapy/intervention

Definition

Mindfulness can be defined as attending to the present moment emotions and thoughts without judgment (Kabat-Zinn et al. 1985). Mindfulness therapies teach clients skills, which have their origins in Buddhist traditions, related to enhanced present-moment awareness and acceptance of thoughts, emotions, and experiences using mindfulness meditation (Baer 2003). Mindfulness has been taught via standardized therapies entirely focused on mindfulness, such as Mindfulness-Based Stress Reduction (MBSR; Kabat-Zinn et al. 1985), as well as integrated into other established therapies including cognitive-behavior therapy (CBT), such as Mindfulness-Based Cognitive Therapy (MBCT; Segal et al. 2002) and Dialectical Behavior Therapy (DBT; Linehan 1993).

Mindfulness therapies have been used with children, adolescents, and adults with ASD. Several programs targeting emotion regulation impairment employed mindfulness-based techniques along with cognitive behavioral (CBT) and other behavioral strategies. A study examining MBSR without adaptation for adults with ASD found increased quality of life, positive

outlook, and mindfulness (Beck et al. 2019). Studies have also utilized adaptations of mindfulness therapies for individuals with ASD, such as shortening the duration of mindfulness meditations and sessions, simplifying instructions, and adapting visual supports. Adapted MBCT has been shown to reduce symptoms of depression, anxiety, and rumination among adults with ASD (Kiep et al. 2015; Spek et al. 2013) and was observed to be equally effective as CBT for depression and anxiety (Sizoo and Kuiper 2017). An individual mindfulness therapy was found to be well-accepted and effective for young adults with ASD who had difficulties with emotion regulation (Conner and White 2018). Lastly, an adaptation of a DBT group targeting emotion regulation and social communication difficulties in adults with ASD found decreased use of suppression and increased reappraisal (Hartmann et al. 2019).

Therapies using mindfulness have also been shown to be effective with children and adolescents with ASD (see Cachia et al. 2016, for review). An emotion regulation-focused adaptation of the Secret Agent Society (Secret Agent Society: Operation Regulation (SAS:OR)) for children with ASD includes mindfulness practices and CBT. A randomized controlled trial comparing SAS:OR to a waitlist control group found improved emotion regulation, decreased problem behaviors (Weiss et al. 2018). Several small studies by Singh et al. (2011a, b) taught a mindfulness practice that was associated with decreased levels of aggression in adolescents with ASD. The Intensive Outpatient Program for Emotion Regulation Treatment is an intensive outpatient program for children with ASD and co-occurring Intellectual Disability which includes mindfulness, CBT, and other behavioral techniques (Shaffer et al. 2019). The intensive outpatient program was found to reduce psychiatric and behavioral symptoms (Shaffer et al. 2019). A pilot open trial of the Emotion Awareness and Skills Enhancement (EASE) program which used mindfulness-based techniques to target impaired emotion regulation among adolescents with ASD observed improvements in emotion regulation, depression, anxiety, and irritability (Conner et al. 2019).

Several studies have involved both parents and children with ASD in interventions. Hwang et al.

(2015) had mothers of children with ASD complete an 8-week mindfulness training prior to teaching their child mindfulness practices. Findings indicated improvements in problem behaviors, parenting stress, and mindful parenting (Hwang et al. 2015). MyMind, a concurrent parent and child mindfulness intervention, has been shown to improve social and communicative skills, decrease internalizing and externalizing problems, improve emotion regulation, and increase adaptive functioning skills in youth and increase mindful parenting and quality of life in parents (de Bruin et al. 2015; Ridderinkhof et al. 2018; Salem-Guirgis et al. 2019). The research on mindfulness therapy in ASD, while preliminary, suggests that mindfulness-based therapies may be useful for a range of treatment targets.

Mindfulness-Based Therapy/Intervention

► Mindfulness Therapy for Individuals with Autism Spectrum Disorder

Mineral Treatments

Susan Hyman
Developmental and Behavioral Pediatrics,
Division Chief Neurodevelopmental and
Behavioral Pediatrics, University of Rochester
Golisano Children's Hospital, Rochester, NY,
USA

Definition

Dietary minerals are chemical elements needed for mammals to maintain basic physiologic functioning. Minerals that are needed in larger

amounts to maintain health (macrominerals) include calcium, phosphorous, magnesium, sodium, potassium, phosphorous, chloride, and sulfur. Lesser amounts of iron, manganese, copper, iodine, zinc, cobalt, fluoride and selenium, and molybdenum are necessary for cellular functioning (trace minerals). Minerals are absorbed from dietary sources. The dietary reference index (DRI) publishes the required intake of minerals for age and gender. If a person with autism spectrum disorder ingests a very restricted diet because of food aversions or is given a restricted diet as a proposed intervention for symptoms of autism, they might be at increased risk for diminished intake of minerals. For example, removal of dairy products from the diet eliminates the major source of calcium in milk products. Calcium is necessary both for bone growth and for many essential biochemical pathways including nerve conduction. Mineral supplementation in individuals with autism might be indicated if there is deficient nutritional intake (Stewart et al. 2015). Many people with/without autism are deficient in the mineral iron. Iron deficiency will ultimately lead to low blood counts or anemia. Prior to that point, lowered iron stores may lead to fatigue and sleep disruption/restless leg syndrome, among other neurobehavioral symptoms. Iron supplementation would be recommended after laboratory documentation of deficiency (Reynolds et al. 2012).

In addition to physiologic replacement of necessary nutrients, a number of controversial therapies provide minerals at amounts greater than recommended by the DRI to target symptoms of autism. Minerals included in novel therapy regimens include magnesium (given with vitamin B6) and zinc. Well-designed clinical trials do not support routine supplementation of minerals at greater than the requirements determined by the DRI.

Blood and hair measurement of minerals has been used without scientific support to date to determine if individuals with autism have altered metabolic requirements for minerals or mineral levels purported to be associated with neurologic symptoms. Laboratory measurement of minerals in blood or hair is not currently a conventional

component of the etiologic workup of individuals with autism. Testing for specific minerals may be necessary when there are suspected toxic exposures such as environmental lead exposure. Elevated lead levels are associated with impaired learning and behavioral challenges. If elevated, chelation may be used medically to remove lead from the blood and body stores. Chelation is a medical procedure advocated by some practitioners for individuals with autism without support of the scientific literature with the goal of increased excretion of heavy metals (a type of mineral) like mercury. There is no scientific evidence at this time that elevated levels of mercury or any other metal are associated with autism. Chelation increases excretion of other minerals from the body as well as the metal of concern and may impact the availability of minerals necessary for routine physiologic functions. Practitioners who prescribe chelation will prescribe supplements containing minerals and trace minerals that may be excreted along with the lead or other metal of concern. Chelation is not a conventional treatment for symptoms of autism and has associated risks although uncommon (James et al. 2015).

Minimal Speech Approach

Kelly Macy

Department of Communication Sciences, The University of Vermont, Burlington, VT, USA

Definition

The minimal speech approach was developed by Potter and Whittaker (2001) to enable communication in children with autism. This approach requires the caregiver or interventionist to use simple speech, consisting of one to three words, usually nouns, which are paired with nonverbal communication. The nonverbal communication can consist of a picture, an object, or a gesture, which help to facilitate comprehension. For example, using the minimal speech approach, the therapist might say “lunch” and point to a picture

communication symbol of a lunch box rather than saying “All right, choice time is over now. We need to put everything away and get ready for lunch. Let’s go.”

In order to create a communication-enabling environment, key characteristics of this approach include reducing the use of speech in all situations, appropriate mapping of single words, giving information in nonverbal ways, minimizing running commentary, delaying the use of speech when teaching new tasks, and avoiding a focus on relative and temporal terms (Potter and Whittaker 2001).

Children with autism often experience confusion when excess speech occurs during communicative interactions. This can lead to anxiety and distress. The simplification of language aims to avert social disengagement and challenging behaviors by facilitating understanding. Potter and Whittaker (2001) found that when a minimal speech approach is used consistently and appropriately, children are more socially responsive and demonstrate more spontaneous communication.

Mirror Neuron System

Ilan Dinstein¹ and Marlene Behrman²

¹Psychology Department, Carnegie Mellon University, Pittsburgh, PA, USA

Structure

Mirror neurons are a unique subset of neurons located in motor areas of the brain, which are thought to play a central role in social communication and imitation. They are active not only during the execution of movements but also during the passive observation of movements made by others. It has been hypothesized that the activity of mirror neurons during observation of movement might represent an internal “motor simulation” of the observed movement. Such a simulation may then be used as a basis for imitating the observed movement or as a gateway for accessing the intentions, goals, and emotions associated with the movement in the mind of the observer. According to the hypothesis, the observer then attributes these intentions and emotions to the observed person in order to interpret their behavior. Individuals with autism have difficulties understanding the intentions, states, and emotions of people around them. It has been suggested that these social difficulties may be caused by the development of abnormal mirror neurons. Despite the large amount of attention that this hypothesis has received in the popular and scientific literatures, the evidence supporting it has been weak and inconsistent. Below is a general overview of mirror neuron research in monkeys and in humans followed by a description of the research related specifically to autism.

Function

Monkey Mirror Neurons

In 1996, Gallese et al. (1996) discovered that about 10% of neurons in ventral premotor area F5 of the macaque monkey respond not only when the monkey executes a particular movement – as expected in this cortical motor area – but also when the monkey passively observes the experimenter performing that very same movement. These visuomotor neurons were named “mirror neurons” because their activity in the brain of the passively observing monkey seems to mirror that of motor neurons active in the person actually executing the movement. Following this initial finding, in 1998, Fogassi et al. (1998) reported that mirror neurons also exist in the inferior parietal lobule (IPL) of the macaque and established the idea of a “mirror system” composed of these two cortical areas.

In these and further studies (Caggiano et al. 2009; Ferrari et al. 2003, 2005; Fogassi et al. 2005; Kohler et al. 2002; Umiltà et al. 2001), mirror neurons were identified based on two critical response characteristics: First, mirror neurons respond in a selective manner to a particular preferred movement such that some neurons respond, for example, only to grasping with the whole hand while others respond only to gripping with the fingertips. In this manner, mirror neuron responses distinguish between different movements in an analogous manner to primary visual cortex neurons that distinguish between different visual stimulus orientations. Second, mirror neurons respond similarly to their preferred movement regardless of whether it is being passively observed or actively executed; thus, the same mirror neuron that responds when the monkey grips with the fingertips also responds when the monkey passively observes someone else gripping with the fingertips. These unique characteristics distinguish mirror neurons from the many other visual, motor, and visuomotor neurons that comprise about 90% of the neurons in areas F5 and IPL of the monkey and are involved in a multitude of visuomotor processes needed for the coordination of movement (Castiello 2005).

The discovery of mirror neurons generated much excitement regarding their possible role in mechanisms of movement understanding and imitation. When we observe someone performing a movement, such as waving their hand to indicate “hello,” how do we instantaneously understand that their intention is to greet us? According to the “simulation theory,” we covertly and unconsciously simulate ourselves performing the movement, then access our own associated intentions and goals for that particular movement and assign them to the person we are observing (Rizzolatti and Craighero 2004). This chain of neural computations supposedly enables us to both understand and ascribe intentionality to others. Mirror neurons have, therefore, been proposed as the physiological mechanism that enables a critical step in this process: precise visual to motor mapping (Rizzolatti and Sinigaglia 2010). Specifically, according to the theory, whenever you observe someone performing an action, particular movement-selective mirror neurons embedded in your motor system are activated, enabling you to simulate yourself performing that movement and to access your own associated intentions and goals (probably through activity of other brain areas, including the limbic system). Taken a step further, mirror neurons can be thought of as a sensorimotor gateway for forming an internal representation of the observed person’s intentions and emotions based on their body language, facial expressions, actions, and so on (Rizzolatti and Craighero 2004; Rizzolatti and Sinigaglia 2010).

It has also been suggested that the same act of motor simulation facilitates imitation and thereby underlies our ability to learn new movements by imitating others (Buccino et al. 2004b; Iacoboni et al. 1999). In this case, covert simulation, which involves activating the precise motor neurons that encode the proper kinematics and dynamics necessary for the execution of the observed movement, may be followed by overt imitation, which involves activating the same neurons along with additional motor neurons that actually command the appropriate muscle contractions.

It is important to note two rather surprising points regarding mirror neuron research in non-human primates. First, all of the described mirror

neurons responded only to object-oriented movements such as grasping or ripping an object. Thus, while the macaque monkey does display several social and communicative movements (e.g., friendliness by lip smacking or threatening by exposing teeth), there have been no reports of mirror neurons responding to such movements as one might have expected if this system was to mediate the representation of other's intentionality. This lack of evidence argues against the suggestion that mirror neurons enable the monkey to understand the intentions and emotions of other monkeys. Second, although macaque monkeys clearly possess mirror neurons, this species does not naturally learn by imitation, except for, perhaps, a very short period at infancy (Ferrari et al. 2006). The absence of imitative behavior in the macaque challenges the hypothesis that mirror neurons enable imitation.

Human Mirror System

The excitement regarding the possible role of mirror neurons in social cognition drove many investigators to search for the human homologue of the monkey mirror system. Early neuroimaging studies utilizing positron emission topography (PET), functional magnetic resonance imaging (fMRI), electroencephalograph (EEG), and magnetoencephalograph (MEG) have applied three types of protocols to elicit mirror neuron responses in humans: passive movement observation, active movement execution, and imitation (simultaneous observation and execution). This section will focus on the fMRI studies because this technique offers the best spatial resolution and offers the strongest evidence regarding the cortical location of responsive neural populations. The discussion below, however, is just as applicable to studies using the other neuroimaging techniques that have generally used the same experimental protocols and the same underlying logic.

In the first protocol, subjects passively viewed images or video clips of movements, such as a smiling face or a hand grasping an object, and their neural responses were compared against a rest condition, following the logic that mirror neurons respond during movement observation and not during rest (Buccino et al. 2001, 2004a;

Iacoboni et al. 2005). In the second protocol, responses during movement execution were recorded to first isolate cortical motor areas and then assess responses to movement observation within these predefined areas (mirror neurons are expected to respond both during observation and execution of a movement). In the third protocol, an imitation condition was added and the responses during imitation were compared with responses during observation and during execution with the logic that mirror neurons should be more active during simultaneous observation and execution than during execution or observation alone (Buccino et al. 2004b; Carr et al. 2003; Grezes et al. 2003; Iacoboni et al. 1999; Leslie et al. 2004; Tanaka and Inui 2002).
